

A characterization of hyperbolic rational maps

CUI Guizhen and TAN Lei, February 2, 2008

Abstract

In the early 1980's Thurston gave a topological characterization of rational maps whose critical points have finite iterated orbits ([Th, DH1]): given a topological branched covering F of the two sphere with finite critical orbits, if F has no Thurston obstructions then F possesses an invariant complex structure (up to isotopy), and is combinatorially equivalent to a rational map.

We extend this theory to the setting of rational maps with infinite critical orbits, assuming a certain kind of hyperbolicity. Our study includes also holomorphic dynamical systems that arise as coverings over disconnected Riemann surfaces of finite type. The obstructions we encounter are similar to those of Thurston. We give concrete criteria for verifying whether or not such obstructions exist.

Among many possible applications, these results can be used for example to construct holomorphic maps with prescribed dynamical properties; or to give a parameter description, both local and global, of bifurcations of complex dynamical systems.

Subject class [2000]: Primary 37F; Secondary 32G.

1 Introduction

Thurston's characterization of postcritically finite rational maps is one of the major tools in complex dynamics. It enables us to produce various kind of rational maps with prescribed dynamical properties, as well as to produce combinatorial models for parameter spaces. There are many applications of Thurston's theory. Just to mention a few, we may cite for example Douady's proof of monotonicity of entropy for unimodal maps ([Do]), Mary Rees' descriptions of parameter spaces (see [Re]), McMullen's rational quotients ([Mc2]), Kiwi's characterization of polynomial laminations (using previous work of Bielefield-Fisher-Hubbard ([BFH]) and Poirier ([Po])), etc.

One drawback of Thurston's theorem is that it can only be applied to postcritically finite rational maps. On one hand, these maps all have a connected Julia set; on the other hand, they form a totally disconnected subset in the parameter space (except the Lattès examples). Therefore the theorem can not characterize the combinatorics of disconnected Julia sets, nor the bifurcations through continuous parameter perturbations.

Over the years, there has been several attempts to extend Thurston's theory beyond postcritically finite maps. For example, David Brown (see [Br]), supported by previous work of Hubbard and Schleicher ([HS]), has succeeded in extending the theory to the uni-critical polynomials with an infinite postcritical set (but always with a connected Julia set), and pushed it even further to the infinite degree case, namely the exponential maps. See also Jiang and Zhang [JZ].

We mention also a recent work of Hubbard-Schleicher-Shishikura [HSS] extending Thurston's theorem to postcritically finite exponential maps.

In this paper, supported by previous works of Cui, Jiang and Sullivan ([CJS]), as well as unpublished manuscripts of Cui, we extend Thurston Theorem to the full setting of arbitrary non-postcritically finite hyperbolic or sub-hyperbolic rational maps. Our analysis leads naturally to the concept of repelling systems over disconnected Riemann surfaces of finitely type, and allows us to establish an analog of Thurston Theorem for these dynamical systems.

This work consists of the first step of a long program, as exposed in [C2], to the study of deformations and bifurcations of rational maps. In a forthcoming paper ([CT]), we will extend our characterization to the setting of geometrically finite rational maps (i.e. maps with parabolic periodic points), and then give a detailed study of their relations with hyperbolic rational maps. A geometrically finite map g often sits on the boundary of several hyperbolic components, and does so in a quite subtle way: if you approach it algebraically, you may or may not get an different geometric limit, depending very much how you approach it. This subtlety makes the study for the deformation of g very difficult. However, it is relatively easy to describe combinatorially all the possible bifurcations. Then, equipped with our Thurston-like realization result, we will be able to prove easily the existence of such bifurcations. For instance we will classify all the hyperbolic components H that contain a path converging to g and that along the path the algebraic and geometric limits coincide. Conversely, given a hyperbolic component H , we will apply our technique to determine all the boundary geometrically finite maps g that are path-accessible from H with the same properties.

Statements

All branched coverings, homeomorphisms in this paper are orientation preserving. Let $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ be an orientation preserving branched covering with degree $\deg G \geq 2$. Its *postcritical set* is defined to be

$$\mathcal{P}_G := \text{closure}\{G^n(c) \mid n > 0, c \text{ a critical point of } G\}.$$

Denote by $\mathcal{P}'_G$ the accumulation set of $\mathcal{P}_G$.

We say that G is *postcritically finite* if every critical point has a finite orbit (i.e. $\mathcal{P}'_G = \emptyset$). We say that G is a **sub-hyperbolic semi-rational map** if $\mathcal{P}'_G$ is finite (or empty); and in case $\mathcal{P}'_G \neq \emptyset$, the map G is holomorphic in a neighborhood of $\mathcal{P}'_G$ and every periodic point in $\mathcal{P}'_G$ is either attracting or super-attracting.

Two sub-hyperbolic semi-rational maps G_1 and G_2 are called *c-equivalent*, if there is a pair (ϕ, ψ) of homeomorphisms of $\overline{\mathbb{C}}$, and a neighborhood U_0 of $\mathcal{P}'_{G_1}$ such that:

- (a) $\phi \circ G_1 = G_2 \circ \psi$;
- (b) ϕ is holomorphic in U_0 ;
- (c) the two maps ϕ and ψ are equal on $\mathcal{P}_{G_1}$, thus on $\mathcal{P}_{G_1} \cup \overline{U_0}$ (by the isolated zero theorem);
- (d) the two maps ϕ and ψ are isotopic to each other rel $\mathcal{P}_{G_1} \cup \overline{U_0}$, i.e., there is a continuous map $H : [0, 1] \times \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ such that each $H(t, \cdot)$ is a homeomorphism of $\overline{\mathbb{C}}$, $H(0, \cdot) = \phi$, $H(1, \cdot) = \psi$, and $H(t, z) \equiv \phi(z)$ for any $t \in [0, 1]$ and any $z \in \mathcal{P}_{G_1} \cup \overline{U_0}$.

Given a sub-hyperbolic semi-rational map G , we consider the problem of whether there is a rational map c -equivalent to it.

Thurston gave a combinatorial criterion of the same problem for postcritically finite branched coverings, based on the absence of Thurston obstructions (see §3.1 and Theorem 3.2 below). We prove here:

Theorem 1.1. *Let G be a sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$. Then G is c -equivalent to a rational map g if and only if G has no Thurston obstruction. In this case the rational map g is unique up to Möbius conjugation.*

The necessity of having no Thurston obstruction, and the unicity of the rational map g , are known to be true for a wider class of maps. See [Mc2] (or Theorem 3.3 below) and [C1].

Thus it remains only to prove the existence part here: i.e. to show that if G is unobstructed then it is c-equivalent to a rational map.

In the process of proving the theorem, we introduce the concept of repelling systems over disconnected Riemann surfaces of finite type, and those of constant complexity. We develop a corresponding Thurston-like theory, including the notions of c-equivalence to holomorphic models, Thurston obstructions, and then a theorem saying that such a system without obstructions is c-equivalent to a holomorphic model (see Theorems 3.5 and 5.4 for detailed statements).

The general strategy of the proof of Theorem 1.1 can be then described as follows: we define K_G , its *filled Julia set* relative to $\mathcal{P}'_G$, to be the set of points not attracted by the cycles in $\mathcal{P}'_G$, i.e.

$$K_G := \{z \in \overline{\mathbb{C}} \mid \overline{\bigcup_{n>0} \{G^n(z)\}} \cap \mathcal{P}'_G = \emptyset\} . \quad (1)$$

Step 0. We show that up to a change of representatives in the c-equivalence class of G , we may assume that G is quasi-regular (Lem. 2.1).

Given now $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ an unobstructed quasi-regular sub-hyperbolic semi-rational map.

1. there is a restriction $G|_{L_1} : L_1 \rightarrow L_0$ in a neighborhood of K_G which is an unobstructed repelling system (Lem. 3.6).
2. there is a sub-repelling system F of $G|_{L_1}$ that is both unobstructed and of constant complexity (Thms. 4.1.(B), 5.1)
3. This repelling system of constant complexity has no boundary obstructions nor renormalized obstructions (Lem. 5.3).
4. Any F with properties in Step 3 is c-equivalent to a holomorphic model (Thm. 5.4).
5. $G|_{L_1} : L_1 \rightarrow L_0$ is c-equivalent to a holomorphic model (Thm. 4.1.(A)).
6. $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ is c-equivalent to a rational map (Prop. 2.4).

Steps 1-3 consist of detailed study of Thurston obstructions for repelling systems, as well as combinatorics of puzzle neighborhoods of K_G .

Step 4 (Theorem 5.4) is the core part of this work. It is proved using Grötzsch inequalities, and, in the presence of renormalizations, Thurston's original Theorem, together with a form of reversed Grötzsch inequality.

Steps 5-6 are standard applications of Measurable Riemann Mapping Theorem.

Steps 2-5 together lead to a Thurston-like theorem for repelling systems (see Theorem 3.5 for a precise statement), which is of independent interest.

Notice that we do not take the approach, as one might have attempted to do, of iteration in an infinite dimensional Teichmüller space.

Remarks. Actually the no-obstruction condition in both our theorem 1.1 and Thurston's original one, is in general a difficult condition to verify, as there are infinitely many candidate obstructions. Therefore in order to apply them effectively, further efforts are often needed. In the postcritically finite setting, many methods have been developed to overcome this

difficulty. But in the case at hand, our result would have been left unsatisfactory if no further criteria have been given. Fortunately, what we have actually proved (see Theorems 5.4 and 9.1 below) does provide more effective criteria. More precisely we will decompose the dynamics into several renormalization pieces that are in fact postcritically finite maps, together with a transition matrix that records the gluing data. This decomposition is not entirely trivial and presents some interests even for rational maps. Our proof shows then that in order to be c -equivalent to a rational map it amounts only to check Thurston's condition for the renormalizations (thus back to the postcritically finite setting), and for the gluing data, which is only one eigenvalue to calculate.

We obtain also a combination result that is very practical to use. We will show in Theorem 9.1 that for any finite collection f_i of rational maps with connected Julia set J_i (postcritically finite or not), together with a compatible (unobstructed) gluing data D , one can glue the f_i 's on neighborhoods of J_i together following D , to obtain a rational map g , so that each f_i appears as a renormalization of g .

For a similar decomposition-gluing approach, we recommend [Pi]. The topology of Julia components for hyperbolic rational maps has been well understood. See [PT].

Theorem 1.1 was already announced in [CJS], together with a sketch of the main ideas of the proof. Numerous details there were however missing, and sometimes erroneous. The presentation here will be totally different. In particular the concept of repelling systems and the related Thurston-like theory are new. This will lead also to two stronger and easier to use results: Theorems 5.4 and 9.1.

Along the proof we will provide numerous supporting diagrams and pertinent examples.

Organization.

The paper is organized as follows: In §2 we prove Step 0 and Step 6 above. We introduce the concept of repelling system and show how it appears as a restriction near K_G of a global map G .

In §3 we first recall the definition of Thurston obstructions and state Thurston's original theorem. We then develop the corresponding concepts for repelling systems and state a Thurston-like theorem in this setting (Theorem 3.5). Assuming it we prove Theorem 1.1 (we just need to do Step 1 above).

In §4 we introduce the concepts of constant complexity repelling systems and the specific obstructions associated to them. We state our Thurston-like theorem, Theorem 5.4, in this setting. Assuming this we complete Steps 2-5 above and proves Theorem 3.5.

In §6-8 we give the proof of Theorem 5.4.

In the final section §9 we state Theorem 9.1.

Acknowledgment. We would like to express our thanks to Xavier Buff, John Hubbard, Yunping Jiang, Carsten Lunde Petersen, Kevin Pilgrim, Mary Rees, Mitsuhiro Shishikura and Dennis Sullivan for helpful comments.

2 Reducing to restrictions near K_G

Let $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ be a sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$, i.e. G is a branched covering such that the cluster set $\mathcal{P}'_G$ of its postcritical set is finite and non-empty, that G is holomorphic in a neighborhood of $\mathcal{P}'_G$, and that every periodic cycle in $\mathcal{P}'_G$ is either attracting or superattracting.

Our objective is to show that if G has no Thurston obstruction then G is c -equivalent to a certain rational map.

2.1 Making the map quasi-regular

Lemma 2.1. *Let G be a sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$. Then G is c -equivalent to a quasi-regular sub-hyperbolic semi-rational map.*

Proof. Consider G as a branched covering from $\overline{\mathbb{C}}$ onto $\overline{\mathbb{C}}$. There is a unique complex structure $\mathcal{X}'$ on $\overline{\mathbb{C}}$ such that $G : (\overline{\mathbb{C}}, \mathcal{X}') \rightarrow \overline{\mathbb{C}}$ is holomorphic (see [DD], section 6.1.10). The uniformization theorem provides thus a conformal homeomorphism $\xi : (\overline{\mathbb{C}}, \mathcal{X}') \rightarrow \overline{\mathbb{C}}$. Set $R := G \circ \xi^{-1}$. Then $R : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ is a branched covering, holomorphic with respect to the standard complex structure, therefore a rational map.

Let $U \subset \overline{\mathbb{C}}$ be a finite union of quasi-discs with mutually disjoint closures, such that $\mathcal{P}'_G \subset U$, $G^{-1}(U) \supset \overline{U}$ and G is holomorphic in a neighborhood of $\overline{U}$ with respect to the standard complex structure. Then the new structure $\mathcal{X}'$ is compatible with the chart $G^{-1}(U)$, so $\xi(U)$ is also a finite disjoint union of quasi-discs. Set $L := \overline{\mathbb{C}} \setminus U$. Then there is a quasi-conformal homeomorphism $\eta : L \rightarrow \xi(L)$ such that $\eta = \xi$ on $(\partial L) \cup (\mathcal{P}_G \cap L)$ and η is isotopic to ξ rel $(\partial L) \cup (\mathcal{P}_G \cap L)$ (see Lemma C.2). Set $\zeta = \eta^{-1} \circ \xi$ on L and $\zeta = id$ on U . Then ζ is isotopic to the identity rel $\overline{U} \cup \mathcal{P}_G$. So $G \circ \zeta^{-1}$ is c -equivalent to G . But $G \circ \zeta^{-1} = R \circ \eta$ on L , with η quasi-conformal and R holomorphic. One sees that $G \circ \zeta^{-1}$ is quasi-regular in L , thus quasi-regular on $\overline{\mathbb{C}}$. $\square$

2.2 Repelling system as restriction

Definition 1. For two subsets E_1, E_2 of $\overline{\mathbb{C}}$, we use the symbol $E_1 \subset\subset E_2$ if the closure of E_1 is contained in the interior of E_2 . We use also $E^c := \overline{\mathbb{C}} \setminus E$ to denote the complement of E in $\overline{\mathbb{C}}$. If $E \subset \overline{\mathbb{C}}$ is compact connected, each complementary component of E (i.e. a component of E^c) is a disc.

We will cover K_G by a suitable puzzle $\mathcal{L}$ so that in particular $G^{-1}(\mathcal{L}) \subset\subset \mathcal{L}$, just as in Branner-Hubbard's study of cubic polynomials with disconnected Julia set (see [BH]). The restriction $G|_{G^{-1}(\mathcal{L})}$, considered as a dynamical system, leads naturally to the concept of repelling systems. Such dynamical systems can be also considered as generalization of Douady-Hubbard's polynomial-like mappings ([DH3]) in two aspects: the domain of definitions will be several components each with several boundary curves (this is necessary as we are dealing with rational maps), and the dynamics will be quasi-regular branched coverings without necessarily analyticity.

Definition 2. We say that $S \subset \overline{\mathbb{C}}$ is a (*quasi-circle*) *bordered Riemann surface* if it is $\overline{\mathbb{C}}$ minus finitely many (might be zero) open quasi-discs D_l so that their closures $\overline{D_l}$ are mutually disjoint. Therefore ∂S is a disjoint union of finitely many (might be zero) quasi-circles. We say that $\mathcal{L} = S_1 \sqcup \cdots \sqcup S_k$ is a *puzzle surface*, if each S_i a bordered Riemann surface, and two distinct S_i and S_j are either contained in distinct copies of the Riemann sphere, or are mutually disjoint. Each S_i is also called an $\mathcal{L}$ -*piece*.

Definition 3. We say that a map $F : \mathcal{E} \rightarrow \mathcal{L}$ is a (**quasi-regular**) **repelling system**, if: $\mathcal{E} \subset\subset \mathcal{L}$ are two nested puzzle surfaces and $F : \mathcal{E} \rightarrow \mathcal{L}$ is a quasi-regular proper mapping; more precisely if $\mathcal{L} = S_1 \sqcup \cdots \sqcup S_k$ is a puzzle surface, $\mathcal{E} := \bigcup_{i,j \in \{1, \dots, k\}, \delta \in \Lambda_{ij}} E_{ij\delta}$ and $F : \mathcal{E} \rightarrow \mathcal{L}$ is a map such that,

- (TOP) for each pair (i, j) , the index set Λ_{ij} is finite or empty, and, for any $\delta \in \Lambda_{ij}$, the set $E_{ij\delta}$ is a bordered Riemann surface compactly contained in the interior of S_i . Furthermore for each i the $E_{ij\delta}$'s are mutually disjoint for all possible choices of j and δ .
- (DYN) $F|_{E_{ij\delta}} : E_{ij\delta} \rightarrow S_j$ is a quasi-regular proper mapping for all possible i, j and δ .

This notion generalizes Douady-Hubbard's polynomial-like maps in both the complexity of the domains and the regularity of the map (recall that $F : \mathcal{E} \rightarrow \mathcal{L}$ is polynomial-like if both $\mathcal{E}$ and $\mathcal{L}$ are connected and simply connected hyperbolic Riemann surfaces with $\mathcal{E} \subset\subset \mathcal{L}$ and if F is an analytic proper mapping). Notice that due to the disconnectedness of the domains the number of preimages $\#F^{-1}(b)$ need not be constant when we let b vary in $\mathcal{L}$.

To a repelling system $F : \mathcal{E} \rightarrow \mathcal{L}$ we associate its **postcritical set** P_F and **filled Julia set** K_F by:

$$\mathcal{P}_F := \text{closure}\{F^n(c) \in \mathcal{L} \mid c \text{ a critical point of } F, n > 0, c, F(c), \dots, F^{n-1}(c) \in \mathcal{E}\};$$

$$K_F := \{z \in \mathcal{E} \mid F^n(z) \in \mathcal{E}, \forall n > 0\}.$$

The set $\mathcal{P}_F$ might be empty, in this case we say that F is unbranched. One may construct examples for which K_F is empty (for example $\mathcal{L} = S_1 \sqcup S_2$, $\mathcal{E} = E_{12} \subset\subset S_1$ and $F(E_{12}) = S_2$), although we will be only interested in the case that $K_F \neq \emptyset$, with either $\mathcal{P}_F = \emptyset$ or not. We have $F^{-1}(K_F) = K_F$, $F(\mathcal{P}_F \cap K_F) \subset \mathcal{P}_F \cap K_F$.

We say furthermore that $F : \mathcal{E} \rightarrow \mathcal{L}$ is *postcritically finite* if $\mathcal{P}_F$ is finite or empty (this is equivalent to say $\#\mathcal{P}_F \cap K_F < \infty$). In particular we say that $F : \mathcal{E} \rightarrow \mathcal{L}$ is an *annuli covering* if each component of $\mathcal{L}$ and $\mathcal{E}$ is a closed annulus, and F is unbranched, i.e. $\mathcal{P}_F = \emptyset$.

A repelling system $F : \mathcal{E} \rightarrow \mathcal{L}$ is *holomorphic* if F is holomorphic in the interior of $\mathcal{E}$.

The following *restriction principle* provides the most fundamental examples of the above concepts:

Lemma 2.2. *Let G be a quasi-regular sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$. Then there exists a puzzle surface neighborhood L_0 of K_G such that, setting $L_1 = G^{-1}(L_0)$,*

$$L_1 \subset\subset L_0, \text{ and } G|_{L_1} : L_1 \rightarrow L_0 \text{ is a postcritically finite repelling system.}$$

Proof. Note that for $S \subset \overline{\mathbb{C}}$ a bordered Riemann surface, a necessary and sufficient condition for each component of $G^{-1}(S)$ to be a bordered Riemann surface is that ∂S does not contain any critical value of G .

One can find an open set U_0 which is the union of a quasi-disc neighborhood for each point of $\mathcal{P}'_G$ so that these quasi-discs have disjoint closures, that ∂U_0 is disjoint from $\mathcal{P}_G$, that G is holomorphic in a neighborhood of $\overline{U_0}$, and that $G(U_0) \subset\subset U_0$.

Set $L_0 = \overline{\mathbb{C}} \setminus U_0$. Then $K_G \subset\subset G^{-1}(L_0) \subset\subset L_0$, $\mathcal{P}_G \cap L_0$ is finite (or empty). This L_0 satisfies the requirement of the lemma. $\square$

Note that one may also set $L_n = G^{-n}(L_0)$ for $n \in \mathbb{N}$, to produce a sequence of repelling systems $G|_{L_{n+1}} : L_{n+1} \rightarrow L_n$ satisfying the requirement of the lemma.

Examples.

- A.** Let $\mathcal{E} \subset\subset \mathcal{L}$ be two closed quasi-discs, and $F : \mathcal{E} \rightarrow \mathcal{L}$ be a holomorphic proper map. Then F is a polynomial-like map in the sense of Douady-Hubbard, K_F is simply the filled Julia set, and $\mathcal{P}_F$ is the postcritical set.

- B.** $\mathcal{L}$ is a closed quasi-disc, $\mathcal{E}$ is the union of finitely many disjoint closed quasi-discs contained in the interior of $\mathcal{L}$, and F maps each $\mathcal{E}$ -piece quasi-conformally onto the larger disc $\mathcal{L}$. In this case $\mathcal{P}_F = \emptyset$ and K_F is the non-escaping set of F . If F is also holomorphic, the filled Julia set K_F is a Cantor set. This happens when F is $z^2 + c$ for large c and $\mathcal{L}$ is a disc in $\mathbb{C}$ bounded by an equipotential such that $0 \in \mathcal{L}$ but $c \notin \mathcal{L}$.
- C.** By convention we may consider $\mathcal{E} = \mathcal{L} = \overline{\mathbb{C}}$ as puzzle surfaces and a quasi-regular postcritically finite branched covering $F : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ as a repelling system.

More important classes of examples are provided by Lemma 2.2, by the annuli coverings (see below). See also §6.1.

Marking. Let $F : \mathcal{E} \rightarrow \mathcal{L}$ be a postcritically finite repelling system. We say that it is *marked*, if it is equipped with a marked set $\mathcal{P}$, satisfying that

$$\mathcal{P}_F \subset \mathcal{P} \subset (\mathcal{L} \setminus \partial\mathcal{L}); \# \mathcal{P} < \infty \text{ and } F(\mathcal{P} \cap \mathcal{E}) \subset \mathcal{P}.$$

If not explicitly mentioned, we will consider F to be marked by its postcritical set $\mathcal{P}_F$.

Motivated by Thurston's theory, we give the following:

Definition 4. We say that two marked postcritically finite repelling systems $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ and $(\mathcal{E}' \xrightarrow{R} \mathcal{L}', \mathcal{P}')$ are **c-equivalent**, if there is a pair of quasi-conformal homeomorphisms $\Phi, \Psi : \mathcal{L} \rightarrow \mathcal{L}'$ such that

$$\left\{ \begin{array}{l} \Psi(\mathcal{E}) = \mathcal{E}' \text{ and } \Psi(\mathcal{P}) = \mathcal{P}' \\ \Psi|_{\partial\mathcal{L} \cup \mathcal{P}} = \Phi|_{\partial\mathcal{L} \cup \mathcal{P}} \\ \Psi \text{ is isotopic to } \Phi \text{ rel } \partial\mathcal{L} \cup \mathcal{P} \\ \Phi \circ F \circ \Psi^{-1}|_{\mathcal{E}'} = R \end{array} \right. \quad \text{in particular} \quad \begin{array}{ccc} \mathcal{L} \supset \mathcal{E} & \xrightarrow{\Psi} & \mathcal{E}' \subset \mathcal{L}' \\ F \downarrow & & \downarrow R \\ \mathcal{L} & \xrightarrow[\Phi]{} & \mathcal{L}' \end{array} \quad \text{commutes.} \quad (2)$$

We say that $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ is **c-equivalent to a holomorphic model**, if there is a holomorphic $(\mathcal{E}' \xrightarrow{R} \mathcal{L}', \mathcal{P}')$ c-equivalent to it.

See §6.1 for examples. We have the following criterion:

Lemma 2.3. *A marked postcritically finite repelling system $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ is c-equivalent to a holomorphic model iff there is a pair (Θ, μ) such that:*

- (a) $\Theta : \mathcal{L} \rightarrow \mathcal{L}$ is a quasi-conformal homeomorphism with $\Theta|_{\partial\mathcal{L} \cup \mathcal{P}} = \text{id}$ and Θ is isotopic to the identity rel $\partial\mathcal{L} \cup \mathcal{P}$.
- (b) μ is a Beltrami differential on $\mathcal{L}$ with $\|\mu\|_\infty < 1$ and $(F \circ \Theta^{-1})^*(\mu) = \mu|_{\Theta(\mathcal{E})}$.

Proof. Assume that $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ is c-equivalent to a holomorphic $(\mathcal{E}' \xrightarrow{R} \mathcal{L}', \mathcal{P}')$. Let (Φ, Ψ) be the pair of quasi-conformal maps given by Definition 4. Set $\Theta = \Phi^{-1} \circ \Psi$. Then Θ satisfies the required isotopic conditions. Let μ be the Beltrami coefficient of Φ . Then (2) means exactly that $(F \circ \Theta^{-1})^*(\mu) = \mu|_{\Theta(\mathcal{E})}$.

Conversely assume the existence of the pair (Θ, μ) . By the Measurable Riemann Mapping Theorem, there is a quasi-conformal map Φ defined piecewisely on $\mathcal{L}$ with Beltrami coefficient μ . Set $\Psi = \Phi \circ \Theta$. Then for $\mathcal{E}' := \Psi(\mathcal{E})$, $\mathcal{P}' = \Psi(\mathcal{P})$, $\mathcal{L}' := \Phi(\mathcal{L})$ and $R := \Phi \circ F \circ \Psi^{-1} : \mathcal{E}' \rightarrow \mathcal{L}'$, we know that $(\mathcal{E}' \xrightarrow{R} \mathcal{L}', \mathcal{P}')$ is a holomorphic repelling system c-equivalent to $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$. $\square$

The following result relates repelling systems to our main interest (Theorem 1.1) through restriction:

Proposition 2.4. *Let G be a quasi-regular sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$. If there is a puzzle surface neighborhood $\mathcal{L}$ of K_G with $G^{-1}(\mathcal{L}) \subset\subset \mathcal{L}$ and $\partial\mathcal{L} \cap \mathcal{P}_G = \emptyset$ such that $G|_{G^{-1}(\mathcal{L})} : G^{-1}(\mathcal{L}) \rightarrow \mathcal{L}$, as a postcritically finite repelling system, is c -equivalent to a holomorphic model, then G is c -equivalent to a rational map.*

Proof. Set $\mathcal{E} = G^{-1}(\mathcal{L})$ and $F = G|_{G^{-1}(\mathcal{L})}$. By assumption F is c -equivalent to a holomorphic model (with marked set $\mathcal{P}_F$, which is equal to $\mathcal{P}_G \cap K_G$). By Lemma 2.3 there is a pair (Θ, μ) , with Θ a quasi-conformal map of $\mathcal{L}$ satisfying $\Theta|_{\partial\mathcal{L} \cup (\mathcal{P}_G \cap \mathcal{L})} = id$ and Θ isotopic to the identity rel $\partial\mathcal{L} \cup (\mathcal{P}_G \cap \mathcal{L})$, with μ a Beltrami differential on $\mathcal{L}$ such that $\|\mu\|_\infty < 1$ and $(G \circ \Theta^{-1})^* \mu = \mu|_{\Theta(\mathcal{E})}$.

Choose U_0 an open neighborhood of $\mathcal{P}'_G$ disjoint from $\mathcal{L}$ so that $G^{-1}(U_0) \supset \overline{U_0}$ and G is holomorphic on $G^{-1}(U_0)$. Set $L_0 = U_0^c$ and $L_n = G^{-n}(L_0)$. As L_n forms a decreasing sequence of sets shrinking down to K_G , there is an integer $N \geq 0$ such that $L_N \subset \mathcal{L}$. So every orbit passing through $L_0 \setminus \mathcal{E}$ stays there for at most $N + 1$ times before being trapped by U_0 .

Extend the map Θ to a quasi-conformal map of $\overline{\mathcal{C}}$ by setting $\Theta := id$ on $\overline{\mathcal{C}} \setminus \mathcal{L}$, then Θ is quasi-conformal and isotopic to the identity rel $\mathcal{P}_G$. Set $G_1 = G \circ \Theta^{-1}$. Then G_1 is again quasi-regular, and is holomorphic on $\Theta(U_0) = U_0$. Clearly, each G_1 -orbit passes through $L_0 \setminus \Theta(\mathcal{E})$ at most $N + 1$ times.

Extend now μ outside $\mathcal{L}$ by $\mu = 0$. Let $\Phi_1 : \overline{\mathcal{C}} \rightarrow \overline{\mathcal{C}}$ be a global integrating map of this extended μ . Set $G_2 := \Phi_1 \circ G_1 \circ \Phi_1^{-1}$. Then G_2 is again quasi-regular, and is holomorphic in the interior of $\Phi_1 \circ \Theta(\mathcal{E})$ and in $\Phi_1(U_0)$. Elsewhere each G_2 -orbit passes at most $N + 1$ times.

One can now apply the Shishikura principle: we spread out the Beltrami differential $\nu_0 \equiv 0$ using iterations of G_2 to get an G_2 -invariant Beltrami differential ν . Note that $\nu = 0$ on $\Phi_1(U_0)$, and $\|\nu\|_\infty < 1$. Integrating ν by a quasi-conformal homeomorphism Φ_2 (necessarily holomorphic on $\Phi_1(U_0)$), we get a new map $R := \Phi_2 \circ G_2 \circ \Phi_2^{-1}$ which is a rational map and is c -equivalent to G_2 , therefore to G . See the following diagram.

$$\begin{array}{ccccccc}
 (\overline{\mathcal{C}}, \mathcal{E}) & \xrightarrow{\Theta} & \overline{\mathcal{C}} & \xrightarrow{\Phi_1} & \overline{\mathcal{C}} & \xrightarrow{\Phi_2} & \overline{\mathcal{C}} \\
 G \downarrow & & \downarrow G_1 & & \downarrow G_2 & & \downarrow R \\
 (\overline{\mathcal{C}}, \mathcal{L}) & \xrightarrow{id} & \overline{\mathcal{C}} & \xrightarrow{\Phi_1} & \overline{\mathcal{C}} & \xrightarrow{\Phi_2} & \overline{\mathcal{C}}
 \end{array}
 \quad \square$$

3 Thurston-like theory for repelling systems

We are thus interested in whether a given repelling system (for example a restriction of G near K_G as in Lemma 2.2) is c -equivalent to a holomorphic model. We will see that, similar to Thurston's theory, the answer is yes if the map has no obstructions that are similar to Thurston's original obstructions.

3.1 Grötzsch inequality and Thurston obstructions

Thurston obstructions are in fact closely related to the Grötzsch inequality on moduli of annuli. The best way to understand them is to start from real models.

1. Slope obstruction. Suppose we want to make a tent map f on $[0, 1]$ with folding point c and with $f(c) > 1$, with left slope d_1 and right slope $-d_2$. This is possible iff $d_1^{-1} + d_2^{-1} < 1$. More generally, suppose we have k disjoint closed intervals $I_1 \sqcup \dots \sqcup I_k$ in $\mathbb{R}$, on which we have a topological dynamical system with the following combinatorics:

For each pair (i, j) , there are finitely many (might be zero) intervals $I_{ij\delta}$, for δ running through some finite or empty index set Λ_{ij} (depending on (i, j)), such that

(TOP) $I_{ij\delta}$ is a sub-interval of I_i , and the $I_{ij\delta}$'s are mutually disjoint for all possible i, j and δ .

(DYN) $f : I_{ij\delta} \rightarrow I_j$ is a homeomorphism for all possible i, j and δ .

The question we ask is: given a collection of slopes (in absolute value) $(d_{ij\delta})_{ij\delta}$, is there a collection of $(I_j, I_{ij\delta}$ and $f : I_{ij\delta} \rightarrow I_j$) so that each $f : I_{ij\delta} \rightarrow I_j$ is affine with slope (in absolute value) $d_{ij\delta}$, for every possible multi-index (i, j, δ) ?

Let us search at first necessary conditions. Assume that such a piece-wise affine map f exists. Then (DYN) implies $|I_{ij\delta}| = \frac{|I_i|}{d_{ij\delta}}$ whereas (TOP) implies $\sum_{j,\delta} |I_{ij\delta}| < |I_i|$. Put these together we get

$$\sum_j \left(\sum_{\delta \in \Lambda_{ij}} \frac{1}{d_{ij\delta}} \right) |I_j| < |I_i|, \quad i = 1, \dots, k. \quad (3)$$

Let $D = (a_{ij})$ denotes the *transition matrix* defined by $a_{ij} := \sum_{\delta \in \Lambda_{ij}} 1/d_{ij\delta}$ (it is a non-negative matrix, with, by convention, $a_{ij} = 0$ if $\Lambda_{ij} = \emptyset$). Then the necessary condition (3) can be reformulated as: $Dv < v$, where $v := (|I_i|)$ is a vector with strictly positive entries.

It is quite easy to check that this necessary condition is also sufficient. Therefore the answer to the above question is: such an affine dynamical system exists if and only if the transition matrix D admits a vector v with strictly positive entries so that $Dv < v$, or equivalently (see Lemma A.1), if and only if the leading eigenvalue $\lambda(D)$ of D from Perron-Frobenius theorem is strictly less than 1.

Once this is done, the following 'complexification' will become easy:

2. Grötzsch obstruction for annuli coverings. Now we may think the intervals I_j are thin tubes, and the subintervals $I_{ij\delta}$ as essential sub-annuli. More precisely, let $\mathcal{A} = A_1 \sqcup \dots \sqcup A_k$ be a puzzle surface with each A_i a closed annulus. For each pair (i, j) , let $(A_{ij\delta})_\delta$ be finitely many (might be zero) sub-annuli of A_i such that

(TOP) $A_{ij\delta}$ is an essential sub-annulus of A_i . Furthermore for each i the $A_{ij\delta}$'s are mutually disjoint for all possible choices of j and δ .

(DYN) $f : A_{ij\delta} \rightarrow A_j$ is a quasi-regular covering of degree $d_{ij\delta}$ for all possible i, j and δ .

Set $\mathcal{E} = \bigsqcup_{ij\delta} A_{ij\delta}$ and consider $f : \mathcal{E} \rightarrow \mathcal{A}$ as an (un)repelling system with empty post-critical set (an annuli covering). The question is: is $f : \mathcal{E} \rightarrow \mathcal{A}$ c-equivalent to a holomorphic model?

Assume that f is already holomorphic. Denote by $|A_*|$ the modulus (rather than the length) of the interior of the annulus A_* . Then $|A_{ij\delta}| = |A_j|/d_{ij\delta}$ (due to (DYN)) and $\sum_{j,\delta} |A_{ij\delta}| < |A_i|$ (due to Grötzsch inequality and (TOP)). Therefore the leading eigenvalue $\lambda(D)$ of the transition matrix D is less than 1. We have, naturally:

Lemma 3.1. *An annuli covering $f : \mathcal{E} \rightarrow \mathcal{A}$ is c-equivalent to a holomorphic model if and only if $\lambda(D) < 1$.*

Proof. $\implies$. Assume $f : \mathcal{E} \rightarrow \mathcal{A}$ is c-equivalent to a holomorphic $R : \mathcal{E}' \rightarrow \mathcal{A}'$. Then the two maps have the same transition matrix D . By the argument above $\lambda(D) < 1$.

$\Leftarrow$. This will be done in Lemma 6.5. $\square$

This Lemma is not needed in the proof of our main result. But it helps the understanding of Thurston obstructions and its proof will shed light to our more complicated situation.

3. Thurston obstruction for a pair $(h, \mathcal{P})$. Let $h : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ be a branched covering, and $\mathcal{P} \subset \overline{\mathbb{C}}$ a closed marked set containing $\mathcal{P}_h$ and $h(\mathcal{P})$. For example we may take h to be a sub-hyperbolic semi-rational map G and $\mathcal{P} = \mathcal{P}_G$.

A Jordan curve γ in $\overline{\mathbb{C}} \setminus \mathcal{P}$ is said *null-homotopic* (resp. *peripheral*) within $\overline{\mathbb{C}} \setminus \mathcal{P}$ if one of its complementary component contains zero (resp. one) point of $\mathcal{P}$; and is said *non-peripheral* within $\overline{\mathbb{C}} \setminus \mathcal{P}$ otherwise, i.e. if each of its two complementary components contains at least two points of $\mathcal{P}$.

We say that $\Gamma = \{\gamma_1, \dots, \gamma_k\}$ is a *multicurve of within* $\overline{\mathbb{C}} \setminus \mathcal{P}$, if each γ_i is a Jordan curve in $\overline{\mathbb{C}} \setminus \mathcal{P}$ and is non-peripheral within $\overline{\mathbb{C}} \setminus \mathcal{P}$, and the γ_j 's are mutually disjoint and mutually non-homotopic within $\overline{\mathbb{C}} \setminus \mathcal{P}$.

Each multicurve Γ induces a $(h, \mathcal{P})$ -transition matrix D_Γ together with its *leading eigenvalue* $\lambda(D_\Gamma)$ as follows: Let $(\gamma_{ij\delta})_{\delta \in \Lambda_{ij}}$ denote the collection of the components of $h^{-1}(\gamma_j)$ homotopic to γ_i within $\overline{\mathbb{C}} \setminus \mathcal{P}$, with Λ_{ij} some finite or empty index set depending on ij . Then $h : \gamma_{ij\delta} \rightarrow \gamma_j$ is a topological covering of a certain degree $d_{ij\delta}$. The transition matrix $D_\Gamma = (a_{ij})$ is defined by $a_{ij} = \sum_{\delta \in \Lambda_{ij}} 1/d_{ij\delta}$ (and $a_{ij} = 0$ if $\Lambda_{ij} = \emptyset$).

We say that a multicurve Γ is $(h, \mathcal{P})$ -stable if every curve of $h^{-1}(\gamma)$, with $\gamma \in \Gamma$, is either null-homotopic or peripheral within $\overline{\mathbb{C}} \setminus \mathcal{P}$, or is homotopic within $\overline{\mathbb{C}} \setminus \mathcal{P}$ to a curve in Γ . This implies that for any $m > 0$, every curve of $h^{-m}(\gamma)$, $\gamma \in \Gamma$ is either null-homotopic or peripheral within $\overline{\mathbb{C}} \setminus \mathcal{P}$, or is homotopic within $\overline{\mathbb{C}} \setminus \mathcal{P}$ to a curve in Γ .

We say that a multicurve Γ is a *Thurston obstruction* for $(h, \mathcal{P})$ if it is $(h, \mathcal{P})$ -stable and $\lambda(D_\Gamma) \geq 1$. In the particular case $\mathcal{P} = \mathcal{P}_h$ we say simply that Γ is a Thurston obstruction for h .

In case that $\mathcal{P}$ is finite (in particular h is postcritically finite) we say that two such pairs $(h, \mathcal{P})$, $(\tilde{h}, \tilde{\mathcal{P}})$ are *c-equivalent* if there is a pair of homeomorphisms $(\phi, \psi) : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ such that $\phi(\mathcal{P}) = \tilde{\mathcal{P}}$, that ϕ is isotopic to ψ rel $\mathcal{P}$, and that $\phi \circ h \circ \psi^{-1} = \tilde{h}$.

Theorem 3.2. (*Marked Thurston theorem*). *Let h be a postcritically finite branched covering of $\overline{\mathbb{C}}$ with $\deg h \geq 2$. Assume that the signature of its orbifold is not $(2, 2, 2, 2)$, or more particularly $\mathcal{P}_h$ contains periodic critical points or at least five points. Let $\mathcal{P}$ be a finite marked set containing $\mathcal{P}_h$ and $h(\mathcal{P})$. If $(h, \mathcal{P})$ has no Thurston obstructions, then $(h, \mathcal{P})$ is c-equivalent to a unique rational map model. More precisely there are homeomorphisms $(\phi, \psi) : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ such that ϕ is isotopic to ψ rel $\mathcal{P}$ and that $f := \phi \circ h \circ \psi^{-1}$ is a rational map. And the conformal conjugacy class of the pair $(f, \phi(\mathcal{P}))$ is unique.*

Furthermore, if h is quasi-regular, both ϕ and ψ can be taken to be quasi-conformal.

Here we omit the definition of orbifold and its signature (see e.g. [DH1]). We mention only that if $\mathcal{P}_h$ contains periodic critical points, or at least 5 points, then the signature of its orbifold is not $(2, 2, 2, 2)$. This is enough for our purpose here.

Remark. Our statement is slightly different than the original Thurston Theorem, where $\mathcal{P} = \mathcal{P}_h$. But the arguments in [DH1] can be easily adapted to prove this more general form. In case h is quasi-regular, we may replace ϕ by a quasi-conformal map ϕ' isotopic to ϕ rel $\mathcal{P}$. This is possible since $\mathcal{P}$ is finite (see Lemma C.2). Lifting this isotopy will provide us a quasi-conformal map ψ' isotopic to ψ rel $\mathcal{P}$ such that $\phi \circ h \circ \psi^{-1} = \phi' \circ h \circ \psi'^{-1}$.

Conversely, we have the following result of McMullen ([Mc2]):

Theorem 3.3. *Let f be a rational map with $\deg f \geq 2$, and let $\mathcal{P}$ be a closed subset such that $f(\mathcal{P}) \subset \mathcal{P}$ and $\mathcal{P}_f \subset \mathcal{P}$. Let Γ be a $(f, \mathcal{P})$ -multicurve whose transition matrix is denoted by D . Then $\lambda(D) \leq 1$. If $\lambda(D) = 1$, then either f is postcritically finite whose orbifold has signature $(2, 2, 2, 2)$; or Γ includes a curve that is contained in the Siegel discs or Herman rings of f .*

Again this form is slightly stronger than McMullen's original version. But the proof goes through without any trouble.

3.2 Thurston obstructions for repelling systems.

Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system, in other words $F : \mathcal{E} \rightarrow \mathcal{L}$ is a quasi-regular branched covering among two nested puzzle surfaces, and $\mathcal{P} \subset \mathcal{L} \setminus \partial\mathcal{L}$ is a finite set containing $\mathcal{P}_F$ and $F(\mathcal{P} \cap \mathcal{E})$. (In case $\mathcal{L} = \overline{\mathbb{C}}$ we are back to Thurston's setting).

Two Jordan curves in $\mathcal{L} \setminus \mathcal{P}$ are *homotopic* if they are both contained in a common $\mathcal{L}$ -piece S and are homotopic to each other within $S \setminus \mathcal{P}$.

A Jordan curve $\gamma \subset \mathcal{L} \setminus \mathcal{P}$ is said *null-homotopic* (resp. *peripheral*) within $\mathcal{L} \setminus \mathcal{P}$ if it bounds an open disc D so that $D \subset \mathcal{L}$ and $D \cap \mathcal{P} = \emptyset$ (resp. $\#D \cap \mathcal{P} = 1$); is said *non-peripheral* within $\mathcal{L} \setminus \mathcal{P}$ otherwise (this is equivalent to say that γ is contained in $S \setminus \mathcal{P}$ for some component S of $\mathcal{L}$, and either γ bounds no disc in S , or γ bounds a disc D in S containing at least two points of $\mathcal{P}$). For example if γ is a boundary curve of an $\mathcal{L}$ -piece S , and if S is not a closed disc, then γ is non-peripheral.

We say that $\Gamma = \{\gamma_1, \dots, \gamma_k\}$ is a *multicurve* within $\mathcal{L} \setminus \mathcal{P}$, if each γ_i is a Jordan curve in $\mathcal{L} \setminus \mathcal{P}$ and is non-peripheral within $\mathcal{L} \setminus \mathcal{P}$, and the γ_j 's are mutually disjoint and mutually non-homotopic within $\mathcal{L} \setminus \mathcal{P}$.

Each multicurve Γ induces an $(F, \mathcal{P})$ -transition matrix $W = W_\Gamma$ together with its *leading eigenvalue* $\lambda(W_\Gamma)$ as follows: Let $(\gamma_{ij\delta})_{\delta \in \Lambda_{ij}}$ denote the collection of the components of $F^{-1}(\gamma_j)$ homotopic to γ_i within $\mathcal{L} \setminus \mathcal{P}$, with Λ_{ij} some finite or empty index set depending on ij . Then $F : \gamma_{ij\delta} \rightarrow \gamma_j$ is a topological covering of a certain degree $d_{ij\delta}$. The transition matrix is defined by

$$W_\Gamma = (b_{ij}), \quad b_{ij} = \sum_{\delta \in \Lambda_{ij}} 1/d_{ij\delta}$$

(with $b_{ij} = 0$ if $\Lambda_{ij} = \emptyset$).

We say that a multicurve Γ within $\mathcal{L} \setminus \mathcal{P}$ is $(F, \mathcal{P})$ -stable if every curve of $F^{-1}(\gamma)$, with $\gamma \in \Gamma$, is either null-homotopic or peripheral within $\mathcal{L} \setminus \mathcal{P}$, or is homotopic within $\mathcal{L} \setminus \mathcal{P}$ to a curve in Γ .

We say that a multicurve Γ within $\mathcal{L} \setminus \mathcal{P}$ is a *Thurston obstruction* for $(F, \mathcal{P})$ if it is $(F, \mathcal{P})$ -stable and $\lambda(W_\Gamma) \geq 1$. See §6.1 for examples.

The following principle will be used frequently, and is a direct consequence of the fact that $F(\mathcal{P} \cap \mathcal{E}) \subset \mathcal{P}$ and that F is a covering over $\mathcal{L} \setminus \mathcal{P}$:

Basic pull-back principle.

1. Let D be an open Jordan disc contained in $\mathcal{L} \setminus \mathcal{P}$ with $\partial D \cap \mathcal{P} = \emptyset$. Then every component of $F^{-1}(D)$ is again an open disc and is contained in $\mathcal{E} \setminus \mathcal{P}$. Each curve in $F^{-1}(\partial D)$ is the boundary of a component of $F^{-1}(D)$.

2. Let A be an open annulus contained in $\mathcal{L} \setminus \mathcal{P}$. Then every component of $F^{-1}(A)$ is again an open annulus and is contained in $\mathcal{E} \setminus \mathcal{P}$.
3. Let D be an open Jordan disc contained in $\mathcal{L}$ with $\partial D \cap \mathcal{P} = \emptyset$ such that D contains a unique point of $\mathcal{P}$. Then every component of $F^{-1}(D)$ is again an open disc, is contained in $\mathcal{E}$, and contains at most one point of $\mathcal{P}$. Each curve in $F^{-1}(\partial D)$ is the boundary of a component of $F^{-1}(D)$.

The following is an easy consequence:

Lemma 3.4. *Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system. For any peripheral (resp. null-homotopic) curve $\gamma \subset \mathcal{L} \setminus \mathcal{P}$, each curve in $F^{-1}(\gamma)$ is either peripheral or null-homotopic (resp. is null-homotopic).*

We will prove:

Theorem 3.5. *(Thurston theorem for marked repelling systems). Let $(\mathcal{B} \xrightarrow{G} \mathcal{M}, \mathcal{Q})$ be a marked postcritically finite repelling system. We assume in addition that no $\mathcal{M}$ -piece is homeomorphic to $\overline{\mathbb{C}}$, in other words we require $\partial S \neq \emptyset$ for every $\mathcal{M}$ -piece S . If $(G, \mathcal{Q})$ has no Thurston obstructions, then $(G, \mathcal{Q})$ is c -equivalent to a holomorphic model map.*

3.3 Proof of Theorem 1.1 using Theorem 3.5

Lemma 3.6. *Assume that $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ is a quasi-regular sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$ and without Thurston obstructions. Then there are puzzle surfaces L_1, L_0 such that*

$$K_G \subset \subset L_1 \subset \subset L_0, \quad G^{-1}(L_0) = L_1$$

and that, the restriction $G|_{L_1} : L_1 \rightarrow L_0$, marked by $\mathcal{P}_G \cap L_0$, is a postcritically finite repelling system without Thurston obstructions.

Proof. One can find an open set U_0 which is the union of a quasi-disc neighborhood for each point of $\mathcal{P}'_G$ so that these quasi-discs have disjoint closures, that ∂U_0 is disjoint from $\mathcal{P}_G$, that G is holomorphic in a neighborhood of $\overline{U_0}$, and that $G(U_0) \subset \subset U_0$. Set $L_0 = U_0^c$. Topologically L_0 is the sphere minus finitely many (open) holes. Set $L_1 = G^{-1}(L_0)$, $H = G|_{L_1}$ and $\mathcal{Q} := \mathcal{P}_G \cap L_0$. So $(H, \mathcal{Q})$ is a marked postcritically finite repelling system. The assumption $\mathcal{P}'_G \neq \emptyset$ implies that $\partial L_0 \neq \emptyset$.

We will show now: under the assumption that $G : \overline{\mathbb{C}} \rightarrow \overline{\mathbb{C}}$ has no Thurston obstructions, the repelling system $(H, \mathcal{Q})$ has no Thurston obstructions.

Assume at first that L_0 is a closed disc containing at most one point of $\mathcal{Q}$. In this case ∂L_0 is a single curve and is null-homotopic or peripheral within $L_0 \setminus \mathcal{Q}$. And there is no multicurve within $L_0 \setminus \mathcal{P}$ as every curve in $L_0 \setminus \mathcal{P}$ is either null-homotopic or peripheral. Consequently $(H, \mathcal{Q})$ has no Thurston obstructions.

Next assume that L_0 is a closed annulus disjoint from $\mathcal{Q}$. Then there is only one class of non-peripheral Jordan curves within $L_0 \setminus \mathcal{Q} = L_0$, namely that of a boundary curve γ of L_0 . But such a γ is also non-peripheral within $\overline{\mathbb{C}} \setminus \mathcal{P}_G$ as each of the two discs of $\overline{\mathbb{C}} \setminus L_0$ contains points of $\mathcal{P}'_G \subset \mathcal{P}_G$. The curves in $G^{-1}(\gamma)$ are either peripheral within L_0 , or homotopic to γ within L_0 . Therefore $\{\gamma\}$ is stable for both $(\overline{\mathbb{C}} \xrightarrow{G} \overline{\mathbb{C}}, \mathcal{P}_G)$ and $(H, \mathcal{Q})$ and the corresponding two transition matrices are identical. By the assumption that $(\overline{\mathbb{C}} \xrightarrow{G} \overline{\mathbb{C}}, \mathcal{P}_G)$ has no Thurston

obstructions, the corresponding leading eigenvalue is less than 1. Therefore $\{\gamma\}$ is not an Thurston obstruction for $(H, \mathcal{Q})$. And $(H, \mathcal{Q})$ has no obstructions.

In the remaining case, L_0 is a bordered Riemann surface, with

$$\#(L_0 \cap \mathcal{Q}) + \#\{\text{boundary curves of } L_0\} \geq 3.$$

In particular each of its boundary curves is non-peripheral within $L_0 \setminus \mathcal{Q}$.

Let now Γ be a multicurve within $L_0 \setminus \mathcal{Q}$. In other words,

- a) each curve in Γ is non-peripheral within $L_0 \setminus \mathcal{Q}$,
- b) the curves in Γ are mutually disjoint,
- c) the curves in Γ are mutually non-homotopic within $L_0 \setminus \mathcal{Q}$.

We want to show that Γ is also a multicurve within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$, i.e. Γ satisfies a), b) and c) with $L_0 \setminus \mathcal{Q}$ replaced by $\overline{\mathcal{C}} \setminus \mathcal{P}_G$. By a), for each curve γ in Γ , either both discs of $\overline{\mathcal{C}} \setminus \gamma$ contains a component of $\overline{\mathcal{C}} \setminus L_0 = U_0$ (therefore infinitely many points of $\mathcal{P}_G$); or one disc of $\overline{\mathcal{C}} \setminus \gamma$ is contained in L_0 and contains at least two points of $\mathcal{Q} \subset \mathcal{P}_G$, while the other disc contains all components of U_0 (therefore infinitely many points of $\mathcal{P}_G$). In both cases each component of $\overline{\mathcal{C}} \setminus \gamma$ contains at least two points of $\mathcal{P}_G$. So γ is non-peripheral within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$.

By b) the curves in Γ are mutually disjoint.

By c), given any two curves γ, γ' of Γ , we have $\gamma, \gamma' \subset L_0 \setminus \mathcal{Q}$ and the open annulus $A(\gamma, \gamma')$ bounded by γ, γ' intersects either U_0 or $\mathcal{Q} \subset \mathcal{P}_G$ (or both). In the former case $A(\gamma, \gamma')$ contains a component of U_0 . Therefore in both cases $A(\gamma, \gamma')$ intersects $\mathcal{P}_G$. So γ, γ' are also non-homotopic within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$.

This arguments implies that Γ is also a multicurve within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$.

Assume now that Γ is a multicurve within $L_0 \setminus \mathcal{Q}$ and is $(H, \mathcal{Q})$ -stable. In other words, for any $\gamma \in \Gamma$ and any curve δ of $G^{-1}(\gamma)$, either δ bounds a disc that is contained in L_0 and that contains at most one point of $\mathcal{Q} = L_0 \cap \mathcal{P}_G$, or δ is homotopic within $L_0 \setminus \mathcal{Q}$ to a curve γ' in Γ . Thus either δ bounds a disc that contains at most one point of $\mathcal{P}_G$, or it is homotopic within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$ to γ' .

This shows that Γ is a multicurve within $\overline{\mathcal{C}} \setminus \mathcal{P}_G$ that is also $(\overline{\mathcal{C}} \xrightarrow{G} \overline{\mathcal{C}}, \mathcal{P}_G)$ -stable. The two transition matrices (by $(H, \mathcal{Q})$ and by $(\overline{\mathcal{C}} \xrightarrow{G} \overline{\mathcal{C}}, \mathcal{P}_G)$) are identical, therefore have the same leading eigenvalue λ .

By the assumption that $(\overline{\mathcal{C}} \xrightarrow{G} \overline{\mathcal{C}}, \mathcal{P}_G)$ has no Thurston obstructions, we know that $\lambda < 1$. So Γ is not a Thurston obstruction for $(H, \mathcal{Q})$.

Therefore $(H, \mathcal{Q})$ has no obstructions. □

Assuming Theorem 3.5, we may now give the

Proof of Theorem 1.1 (the existence part). Let G be sub-hyperbolic semi-rational map with $\mathcal{P}'_G \neq \emptyset$ and without Thurston obstruction. We may assume in addition that G is globally quasi-regular, up to a change of representatives in its c-equivalence class (by Lemma 2.1).

We may then apply Lemma 3.6 to G to show that it has a restriction near K_G which is a postcritically finite repelling system without Thurston obstructions, therefore is c-equivalent to a holomorphic model by Theorem 3.5. We may then apply Proposition 2.4 to conclude that G is c-equivalent to a rational map. □

4 Reduction to a sub-repelling system

Our main objective here is:

Theorem 4.1. *Let $(\mathcal{B} \xrightarrow{G} \mathcal{M}, \mathcal{Q})$ be a marked postcritically finite repelling system such that every $\mathcal{M}$ -piece has a non-empty boundary.*

Let $\mathcal{E}, \mathcal{L}$ be two puzzle surface neighborhoods of K_G satisfying:

- (*) $K_G \subset \subset \mathcal{E} \subset \subset \mathcal{L} \subset \subset \mathcal{M}$, $\mathcal{E} = G^{-1}(\mathcal{L})$, $\mathcal{Q} \cap \partial \mathcal{L} = \emptyset$;
- (**) *for every $\mathcal{L}$ -piece S , and for the $\mathcal{M}$ -piece S_0 containing S in the interior, and for the copy $\overline{\mathcal{C}}$ of the Riemann sphere containing S_0 (therefore S), every (disc-like) component of $\overline{\mathcal{C}} \setminus S$ contains either components of ∂S_0 or points of $\mathcal{Q}$ (or both);*

Let $F = G|_{\mathcal{E}} : \mathcal{E} \rightarrow \mathcal{L}$ be the sub-repelling system marked by $\mathcal{Q} \cap \mathcal{L}$. Then,

- (A) *If $(F, \mathcal{Q} \cap \mathcal{L})$ is c-equivalent to a holomorphic model so is $(G, \mathcal{Q})$.*
- (B) *If $(G, \mathcal{Q})$ has no Thurston obstructions, so does $(F, \mathcal{Q} \cap \mathcal{L})$.*

$$\begin{array}{ccc}
 G \text{ has no ob.} & & G \sim_c \text{ hol. model} \\
 \Downarrow \text{ (B)} & & \Uparrow \text{ (A)} \\
 F \text{ has no ob.} & \xRightarrow{?} & F \sim_c \text{ hol. model.}
 \end{array}$$

Once the theorem is proved the problem of c-equivalence to a holomorphic model for $(G, \mathcal{Q})$ is reduced the problem for a suitable sub-repelling system.

4.1 How to get a stable multicurve

The following criterion is very useful:

Lemma 4.2. *A marked postcritically finite repelling system $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ has a Thurston obstruction if and only if there is a multicurve Γ' within $\mathcal{L} \setminus \mathcal{P}$ (not necessarily $(F, \mathcal{P})$ -stable) with $\lambda(W_{\Gamma'}) \geq 1$.*

Proof. We will need to produce an $(F, \mathcal{P})$ -stable multicurve with the leading eigenvalue of its transition matrix greater than one.

Let Γ be a multicurve within $\mathcal{L} \setminus \mathcal{P}$, i.e. the curves in Γ are non-peripheral, mutually disjoint and mutually non-homotopic within $\mathcal{L} \setminus \mathcal{P}$. The action of $(F, \mathcal{P})$ induces a directed graph Λ_Γ as follows: the vertices are the curves in Γ . And there is an edge directing from δ to γ (maybe $\delta = \gamma$) if δ is homotopic to a curve in $F^{-1}(\gamma)$ within $\mathcal{L} \setminus \mathcal{P}$.

If $A \subset \Gamma$ is a sub-multicurve then W_A is the submatrix of W_Γ corresponding to the entries of A , denoted by $W_\Gamma|_A$, and Λ_A is the corresponding subgraph of Λ_Γ . In this case $\lambda(W_A) \leq \lambda(W_\Gamma)$ (by Lemma A.3).

We will say that a multicurve A within $\mathcal{L} \setminus \mathcal{P}$ is *irreducible* if any two vertices of its graph Λ_A can be connected by following successively the directed edges. It is elementary that if $\lambda(W_\Gamma) > 0$ then there is an irreducible sub-multicurve $A \subset \Gamma$ with $\lambda(W_A) = \lambda(W_\Gamma)$.

Each multicurve Γ defines a pulled-back multicurve Γ_1 as follows: The curves in $F^{-1}(\Gamma) := \bigcup_{\gamma \in \Gamma} F^{-1}(\gamma)$ are already mutually disjoint. But some of them might be peripheral, or homotopic to another within $\mathcal{L} \setminus \mathcal{P}$. Pick one representative in each homotopic class of the non-peripheral curves in $F^{-1}(\Gamma)$. Together they form a new multicurve, Γ_1 .

In general a curve in Γ_1 might not be homotopically disjoint from a curve in Γ .

Saying that Γ is stable is equivalent to say that every curve in Γ_1 is homotopic to a curve in Γ .

In case that every vertex of Λ_Γ is the departure of an edge (for example when Γ is irreducible), then every curve in Γ is homotopic to a curve in Γ_1 . One obtains then successive pulled back multicurves $\Gamma_2, \dots$, such that curves in Γ_i are homotopic to curves in Γ_{i+1} . As $\mathcal{L} \setminus \mathcal{P}$ is topologically finite, there is N such that $\#\Gamma_N = \#\Gamma_{N+1}$. Consequently Γ_N is $(F, \mathcal{P})$ -stable.

Assume now Γ' is a multicurve within $\mathcal{L} \setminus \mathcal{P}$, not necessarily stable, such that $\lambda(W_{\Gamma'}) \geq 1$.

There there is an irreducible sub-multicurve $A \subset \Gamma'$ with $\lambda(W_A) = \lambda(W_{\Gamma'})$. Pulling back successively A we get a multicurve A_N that is $(F, \mathcal{P})$ -stable and contains A . And $1 \leq \lambda(W_{\Gamma'}) = \lambda(W_A) \leq \lambda(W_{A_N})$. $\square$

4.2 Proof of Theorem 4.1

Proof of Theorem 4.1.

(A). This part can be proved similarly as Proposition 2.4. We will omit the details here.

(B). Note that Condition (**) assures a certain minimality of $\mathcal{L}$, so that $\mathcal{L}$ does not have trivial holes in $\mathcal{M}$.

Set $\mathcal{P} = \mathcal{Q} \cap \mathcal{L}$, the marked set of F .

At first we prove the following facts that will be used frequently in the sequel:

- (a) Two Jordan curves γ, γ' in $\mathcal{L} \setminus \mathcal{P}$, homotopic within $\mathcal{L} \setminus \mathcal{P}$, are also homotopic within $\mathcal{M} \setminus \mathcal{Q}$.
- (b) For a Jordan curve γ in $\mathcal{L} \setminus \mathcal{P}$, it is null-homotopic within $\mathcal{L} \setminus \mathcal{P}$ iff it is null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$.
- (c) A peripheral curve within $\mathcal{L} \setminus \mathcal{P}$ is also peripheral within $\mathcal{M} \setminus \mathcal{Q}$.

Proof. (a). There is an $\mathcal{L}$ -piece S containing both γ, γ' and γ and γ' are homotopic within $S \setminus \mathcal{P}$. But S is contained in an $\mathcal{M}$ -piece S_0 , and $\mathcal{P} \cap S = \mathcal{Q} \cap \mathcal{L} \cap S = \mathcal{Q} \cap S$. So $S \setminus \mathcal{P} \subset S_0 \setminus \mathcal{Q}$ and γ and γ' are homotopic within $S_0 \setminus \mathcal{Q}$, therefore within $\mathcal{M} \setminus \mathcal{Q}$.

(b). Again let S (resp. S_0) be the $\mathcal{L}$ -piece (resp. $\mathcal{M}$ -piece) containing γ .

If γ is null-homotopic within $\mathcal{L} \setminus \mathcal{P}$ then it bounds a disc D contained in $S \setminus \mathcal{P}$. But $S \setminus \mathcal{P} \subset S_0 \setminus \mathcal{Q}$. So $D \subset S_0 \setminus \mathcal{Q}$ and γ is null-homotopic within $S_0 \setminus \mathcal{Q}$, therefore within $\mathcal{M} \setminus \mathcal{Q}$.

Conversely if γ is null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$, it bounds an open disc D contained in $S_0 \setminus \mathcal{Q}$. If D is not contained in S , and as $\gamma = \partial D \subset S$, we must have that D contains a component of $\overline{\mathbb{C}} \setminus S$. By Condition (**) we know that D intersects $\partial S_0 \cup \mathcal{Q}$. This contradicts the fact that $D \subset S_0 \setminus \mathcal{Q}$. Therefore $D \subset S$. But $D \cap \mathcal{Q} = \emptyset$. So $D \subset S \setminus \mathcal{Q} = S \setminus \mathcal{P}$. Therefore γ is also null-homotopic within $S \setminus \mathcal{P}$, hence within $\mathcal{L} \setminus \mathcal{P}$.

(c). By definition γ is peripheral within $\mathcal{L} \setminus \mathcal{P}$ if it bounds a disc D that is contained in an $\mathcal{L}$ -piece S such that $\#D \cap \mathcal{P} = 1$. In this case D is also contained in the $\mathcal{M}$ -piece S_0 that contains S , and $\#D \cap \mathcal{Q} = \#D \cap (\mathcal{Q} \cap S) = \#D \cap \mathcal{P} = 1$. By definition again γ is also peripheral within $\mathcal{M} \setminus \mathcal{Q}$. $\square$

Assume now that $(G, \mathcal{Q})$ has no Thurston obstructions. We will prove that $(F, \mathcal{P})$ has no obstructions either.

Let T be a multicurve within $\mathcal{L} \setminus \mathcal{P}$, i.e.:

- i) each curve in T is non-peripheral within $\mathcal{L} \setminus \mathcal{P}$;
- ii) the curves in T are mutually disjoint;
- iii) the curves in T are mutually non-homotopic within $\mathcal{L} \setminus \mathcal{P}$.

Change the representatives within the same homotopy classes if necessary, we may assume in addition:

- iv) a curve in T is either equal to a boundary curve of $\mathcal{L}$, or, is disjoint from $\partial \mathcal{L}$ and is not homotopic to a curve in $\partial \mathcal{L}$ within $\mathcal{L} \setminus \mathcal{P}$.

When considering homotopy within $\mathcal{M} \setminus \mathcal{Q}$ (which contains $\mathcal{L} \setminus \mathcal{P}$), there are two new phenomena:

1. Some of the curves in T may now become peripheral (but never null-homotopic) within $\mathcal{M} \setminus \mathcal{Q}$ (Figure 1 shows how this may happen).
2. Some of the curves in T may now become homotopic to each other within $\mathcal{M} \setminus \mathcal{Q}$.

The following two parts treat each phenomenon separately:

1. Curves in T that become peripheral within $\mathcal{M} \setminus \mathcal{Q}$.

Figure 1: The curve γ is not peripheral within $\mathcal{L} \setminus \mathcal{P}$ but is peripheral within $\mathcal{M} \setminus \mathcal{Q}$, as it bounds a disc $D(\gamma)$ that is contained in $\mathcal{M}$ and contains a unique point of $\mathcal{Q}$.

We now consider homotopy within $\mathcal{M} \setminus \mathcal{Q}$. By (b) each curve in T is non-null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$, is therefore either peripheral or non-peripheral within $\mathcal{M} \setminus \mathcal{Q}$. We thus decompose T into $T = Z \sqcup X$, with Z (resp. X) denoting the collection of curves in T that are peripheral (resp. non-peripheral) within $\mathcal{M} \setminus \mathcal{Q}$. Denote by W_Z, W_X the $(F, \mathcal{P})$ -transition matrix of Z, X respectively.

Lemma I. The $(F, \mathcal{P})$ -transition matrix W_T has the following block decomposition (where O denotes a rectangle zero-matrix): $W_T = \begin{pmatrix} W_X & O \\ * & W_Z \end{pmatrix}$.

Proof. Let $\gamma \in Z$ and β be a curve of $F^{-1}(\gamma) = G^{-1}(\gamma)$. We just need to show that if β is homotopic within $\mathcal{L} \setminus \mathcal{P}$ to a curve γ' in T , then $\gamma' \in Z$.

By definition of Z the curve γ bounds an open disc $D(\gamma)$ contained in $\mathcal{M}$ and containing a unique point of $\mathcal{Q}$. Therefore, applying the Basic pull-back principle to $D(\gamma)$, we know that each component of $G^{-1}(D(\gamma))$ is disc-like, is contained in $\mathcal{B} = G^{-1}(\mathcal{M})$, and contains at most one point of $\mathcal{Q}$. Let β be a curve in $G^{-1}(\gamma)$. Then β is the boundary of a component of $G^{-1}(D(\gamma))$. So β is either null-homotopic or peripheral (within $\mathcal{M} \setminus \mathcal{Q}$). On the other hand, β is homotopic within $\mathcal{L} \setminus \mathcal{P}$ to $\gamma' \in T$ by assumption. And the homotopy can be taken within $\mathcal{M} \setminus \mathcal{Q}$ by (a). Consequently γ' is either null-homotopic or peripheral within $\mathcal{M} \setminus \mathcal{Q}$.

But no curves in T are null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$ (by (b) and by the definition of T), so both β and γ' are peripheral within $\mathcal{M} \setminus \mathcal{Q}$. Therefore $\gamma' \in Z$. $\square$

Lemma II. Each curve of Z is a boundary curve of $\mathcal{L}$.

Proof. Let $\gamma \in T$ that is not a boundary curve of $\mathcal{L}$. We just need to show that γ is necessarily non-peripheral within $\mathcal{M} \setminus \mathcal{Q}$.

There is an $\mathcal{L}$ -piece S , an $\mathcal{M}$ -piece S_0 and a Riemann sphere $\overline{\mathcal{C}}$ such that γ is contained in the interior of S and $S \subset \subset S_0 \subsetneq \overline{\mathcal{C}}$. Now $\overline{\mathcal{C}} \setminus \gamma$ has two disc components D_1, D_2 .

By i) either one disc, say D_1 , is contained in S and contains at least two points of $\mathcal{P} \subset \mathcal{Q}$, or both D_1, D_2 intersect $\overline{\mathcal{C}} \setminus S$.

In the former case, $D_1 \subset S \subset S_0$, so D_2 contains ∂S_0 , which by assumption is non-empty. This implies that γ is non-peripheral within $S_0 \setminus \mathcal{Q}$.

In the latter case, as $\gamma \subset S$, each D_i contains a component of $\overline{\mathcal{C}} \setminus S$. By Condition (**), each D_i contains either a curve in ∂S_0 or points in $\mathcal{Q}$ (or both). Assume by contradiction that γ is peripheral within $S_0 \setminus \mathcal{Q}$. Then one of D_1, D_2 , denoted by D , contains a unique point of $\mathcal{Q}$ and no boundary component of S_0 . We have $D \subset S_0$. But γ is not peripheral within $S \setminus \mathcal{P}$ by i). So D is not contained in S . Therefore D contains components of $\overline{\mathcal{C}} \setminus S$. Let Δ be one component of $\overline{\mathcal{C}} \setminus S$ contained in D . Then Δ is bounded by a curve δ which is also a boundary curve of S . By Condition (**) again Δ must intersect $\partial S_0 \cup \mathcal{Q}$. But $\Delta \subset D \subset S_0$. So $\Delta \cap \partial S_0 = \emptyset$. On the other hand, $D \cap \mathcal{Q}$ consists of a single point, denoted by a . So $a \in \Delta$. This shows that D contains a unique component of $\overline{\mathcal{C}} \setminus S$. By iv) $\gamma \cap \partial S = \emptyset$, so D contains a unique boundary curve of S , which must be δ . Furthermore the annulus $A(\gamma, \delta)$ does not contain a . Therefore $A(\gamma, \delta) \subset S$ and

$$A(\gamma, \delta) \subset D \setminus \{a\} = D \setminus \mathcal{Q} \subset D \setminus \mathcal{P}.$$

So $A(\gamma, \delta) \subset S \setminus \mathcal{P}$. This means that the boundary curve δ of S is homotopic to γ within $S \setminus \mathcal{P}$. This is not possible by iv). $\square$

Lemma III. There is a power $q \geq 1$ such that $(W_Z)^q = O$. Therefore $\lambda(W_Z) = 0$ and $\lambda(W_X) = \lambda(W_T)$.

Proof. Let $\mathcal{G}$ be the union of Z with the curves in $\partial \mathcal{L}$ that are peripheral within $\mathcal{L} \setminus \mathcal{P}$ (these added curves are disjoint from curves in Z by i) and iv)). By Claim II every curve in $\mathcal{G}$ is a boundary curve of $\mathcal{L}$.

By definition a curve $\gamma \in \partial \mathcal{L}$ is peripheral if it is the boundary of an $\mathcal{L}$ -piece $D(\gamma)$ (therefore $D(\gamma)$ is a disc) with $\#D(\gamma) \cap \mathcal{P} = 1$. Note that $D(\gamma) \subset \mathcal{L} \subset \mathcal{M}$.

Let $\gamma \in \mathcal{G}$. Then γ bounds a disc $D(\gamma)$ which is contained in $\mathcal{M}$ and which contains a unique point $a(\gamma)$ of $\mathcal{Q}$.

We decompose $\mathcal{G}$ into $\mathcal{G}_p \sqcup \mathcal{G}_0$ according to $a(\gamma)$ is periodic or not.

By Basic pull-back principle, for all $k \geq 1$, the components of $G^{-k}(D(\gamma))$ are all disc-like, and each is bounded by exactly one curve of $G^{-k}(\gamma)$.

Assume $\gamma \in \mathcal{G}_0$, so that $a(\gamma)$ is not periodic (as G is postcritically finite, the orbit of $a(\gamma)$ is either preperiodic or eventually escapes $\mathcal{B}$). Then there is an integer $k(\gamma) \geq 1$ such that $G^{-k(\gamma)}(a(\gamma))$ contains no points of $\mathcal{Q}$. But $G^{-k}(D(\gamma)) \cap \mathcal{Q} \subset G^{-k(\gamma)}(a(\gamma))$. So $G^{-k(\gamma)}(D(\gamma)) \cap \mathcal{Q} = \emptyset$. Thus the curves in $G^{-k(\gamma)}(\gamma)$ are null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$ and hence are null-homotopic within $\mathcal{L} \setminus \mathcal{P}$ by (b). Therefore for all $k \geq k(\gamma)$, the curves in $G^{-k}(\gamma)$ are all null-homotopic within $\mathcal{L} \setminus \mathcal{P}$.

There is therefore a common integer k , so that for every $\gamma \in \mathcal{G}_0$, the curves in $G^{-k}(\gamma)$ are all null-homotopic within $\mathcal{L} \setminus \mathcal{P}$.

Let now $\gamma \in \mathcal{G}_p$, i.e. with $a(\gamma)$ periodic. Set $a = a(\gamma)$. Denote by p its period. This implies in particular that the orbit of a does not escape $\mathcal{M}$, so $a \in K_G = K_F \subset \mathcal{L}$.

Denote by $\{\eta_1, \dots, \eta_m\}$ the curves in $\mathcal{G}$ homotopic to γ within $\mathcal{M} \setminus \mathcal{Q}$, i.e. each η_j bounds a disc $D(\eta_j)$ which is contained in $\mathcal{M}$ with $D(\eta_j) \cap \mathcal{Q} = \{a\}$. As $\eta_i \cap \eta_j = \emptyset$ for $i \neq j$, we have either $D(\eta_i) \subset D(\eta_j)$ or $D(\eta_i) \supset D(\eta_j)$. We numerate the η_j 's in the increasing order, i.e. such that $D(\eta_j)$ contains $D(\eta_{j-1})$ and η_{j-1} . The smallest disc $D(\eta_1)$ must be contained in $\mathcal{L}$, since there is no curve in $\partial\mathcal{L}$ separating $a \in \mathcal{L}$ from $\eta_1 \subset \partial\mathcal{L}$. Therefore $\overline{D}(\eta_1)$ is an $\mathcal{L}$ -piece, and η_1 is peripheral within $\mathcal{L} \setminus \mathcal{P}$.

Fix $j \in \{1, \dots, m\}$. The components of $G^{-p}(D(\eta_j))$ are all disc-like, with one of them, denoted by $D(\beta_j)$, containing a , and the others containing a preimage of a that is not periodic.

Therefore $G^{-p}(\eta_j) = F^{-p}(\eta_j)$ has a unique component β_j , which is the boundary of $D(\beta_j)$, homotopic to γ (and to $\{a\}$) within $\mathcal{M} \setminus \mathcal{Q}$, and the other components are either null-homotopic or homotopic within $\mathcal{L} \setminus \mathcal{P}$ to a curve in $\mathcal{G}_0$.

Claim. $\overline{D}(\beta_1) \subset D(\eta_1)$ and $\overline{D}(\beta_j) \subset D(\eta_{j-1})$ for $j = 2, \dots, m$.

Proof. At first the enlarged collection of curves $\{\eta_1, \dots, \eta_m, \beta_1, \dots, \beta_m\}$ are mutually disjoint. This is clearly true between the η_j 's and between the β_j 's. But $\beta_j \cap \eta_i = \emptyset$ as well, as $\eta_i \subset \partial\mathcal{L}$, $\beta_j \subset F^{-p}(\mathcal{L})$ and $F^{-p}(\mathcal{L})$ is contained in the interior of $\mathcal{L}$.

Therefore the discs $D(\eta_i)$, $D(\beta_j)$ are nested in a certain order.

We prove now that $\beta_j \subset D(\eta_j)$ for $j = 1, \dots, m$.

We prove it at first for β_1 . Note that β_1 is the boundary of E_1 , the component of $F^{-p}(\overline{D}(\eta_1))$ containing a . But $F^{-p}(\mathcal{L})$ is contained in the interior of $\mathcal{L}$, so E_1 is contained in the interior of an $\mathcal{L}$ -piece, which must be $\overline{D}(\eta_1)$, i.e. $\beta_1 \subset D(\eta_1)$.

Assume by contradiction that there is a minimal integer $j \geq 2$ such that $\beta_j \not\subset D(\eta_j)$. Then $\beta_j \cap \overline{D}_j = \emptyset$ (due to again, $F^{-p}(\mathcal{L}) \cap \partial\mathcal{L} = \emptyset$). The annulus $A(\eta_j, \eta_{j-1})$ is contained in $D(\eta_j)$ therefore in $\mathcal{M}$. So its inverse images by G are well defined. By the Basic pull-back principle the components of $G^{-p}(A(\eta_j, \eta_{j-1}))$ are all annuli. One of them must be $A(\beta_j, \beta_{j-1})$, which contains $A(\eta_j, \eta_{j-1})$ as a sub-annulus. Therefore

$$G^m(A(\eta_j, \eta_{j-1})), \quad m = 0, \dots, p-1$$

are all contained in $\mathcal{B} = G^{-1}(\mathcal{M})$. Set $A' = \bigcup_{m=0}^{p-1} G^m(A(\eta_j, \eta_{j-1}))$. Then $G(A') \subset A'$. Trivially either $\overline{A}(\eta_j, \eta_{j-1})$ is an $\mathcal{L}$ -piece or there is a point $z \in A(\eta_j, \eta_{j-1}) \cap (\mathcal{B} \setminus \mathcal{L})$. The former case is not possible, as components of $F^{-p}(\mathcal{L})$ are compactly contained in $\mathcal{L}$. In the latter case, the G -orbit of z never escapes A' which is a subset of $\mathcal{B}$, so $z \in K_G$. This is again impossible as $K_G = K_F \subset \mathcal{L}$ and $z \notin \mathcal{L}$.

This proves that $\beta_j \subset D(\eta_j)$ for all $j = 1, \dots, m$. It follows that $\overline{D}(\beta_j) \subset D(\eta_j)$.

Fix $j = 1, \dots, m$. Denote by S_j the $\mathcal{L}$ -piece containing η_j as a boundary curve. Thus $S_1 = D(\eta_1)$. We want to show now for $j \geq 2$ either $S_j \cap D(\eta_j) = \emptyset$ or $S_j = \overline{A}(\eta_j, \eta_{j-1})$.

Assume $S_j \cap D(\eta_j) \neq \emptyset$. We have $S_j \subset \overline{D}_j \setminus \{a\}$. Then $\eta_{j-1} \subset \partial S_j$ since no curve in $\partial \mathcal{L}$ separates η_j from η_{j-1} . So $S_j \subset \overline{A}(\eta_j, \eta_{j-1}) \subset \mathcal{M} \setminus \mathcal{Q}$. But S_j can not have other boundary curves due to Condition (**). Therefore $S_j = \overline{A}(\eta_j, \eta_{j-1})$.

It follows $S_2 = S_3 = \overline{A}(\eta_2, \eta_3)$, and more generally $S_j = S_{j+1} = \overline{A}(\eta_j, \eta_{j+1})$ for any even number j with $2 \leq j < m$.

Fix $j = 1, \dots, m$. We have $\beta_j \subset F^{-p}(\mathcal{L}) \subset \mathcal{L}$. Let S' be the $\mathcal{L}$ -piece containing β_j . We want to show that S' is one of S_i .

If $\beta_j \subset D(\eta_1)$ then $S' = D(\eta_1) = S_1$. Otherwise S' has a boundary component η separating a from β . Therefore η is one of η_i and $S' = S_i$.

Let now j be an even number with $2 \leq j < m$. We know that $\beta_j \subset D(\eta_j)$ and $\beta_j \subset S_i$ for some i . Therefore $S_i \subset \overline{D}(\eta_{j-1})$. But $\beta_j \cap \eta_{j-1} = \emptyset$. So $\beta_j \subset D(\eta_{j-1})$. Furthermore, $\overline{A}(\beta_j, \beta_{j+1})$ is a component of $F^{-p}(S_j)$, so must be contained entirely in the $\mathcal{L}$ -piece S_i . Therefore $\beta_{j+1} \subset \overline{D}(\eta_{j-1})$ and consequently $\beta_{j+1} \subset D(\eta_{j-1})$.

This ends the proof of the claim: $\overline{D}(\beta_j) \subset D(\eta_{j-1})$ for any $j \geq 2$.

Note that in each component of $G^{-p}(D(\eta_m))$ the G^p -preimages of the discs $D(\eta_i)$, $D(\beta_j)$ are nested in the same order. There is therefore q_j , such that for any $n \geq q_j$, all curves of $G^{-np}(\eta_j)$ are either null-homotopic or homotopic within $\overline{D}(\eta_1) \setminus \{a\}$, therefore within $\mathcal{L} \setminus \mathcal{P}$, to η_1 , which is a curve in $\partial \mathcal{R}$.

Combining these arguments together, we find a q , such that every curve in $F^{-q}(\mathcal{G})$ is either null-homotopic or homotopic within $\mathcal{L} \setminus \mathcal{P}$ to a curve in $\partial \mathcal{R}$. So $(W_Z)^q = O$.

Therefore $\lambda(W_Z) = 0$ and $\lambda(W_X) = \lambda(W_T)$. $\square$

2. Curves in X that are homotopic to each other within $\mathcal{M} \setminus \mathcal{Q}$. Now we decompose $X = T \setminus Z$ into $X_1 \sqcup \dots \sqcup X_k$ according to the homotopy within $\mathcal{M} \setminus \mathcal{Q}$, i.e., two curves in X are homotopic within $\mathcal{M} \setminus \mathcal{Q}$ if and only if they belong to some subset X_i . Pick one curve γ_i in each X_i and set $\Gamma := \{\gamma_1, \dots, \gamma_k\}$. Clearly Γ is a multicurve within $\mathcal{M} \setminus \mathcal{Q}$.

Set $D_\Gamma := (b_{ij})$ the $(G, \mathcal{Q})$ -transition matrix of Γ . Set $W_X := (a_{\delta\beta})$. By definition

$$b_{ij} = \sum_{\alpha \in \mathcal{G}_{ij}} \frac{1}{\deg(G : \alpha \rightarrow \gamma_j)} \quad \text{and} \quad a_{\delta\beta} = \sum_{\alpha \in \mathcal{F}_{\delta\beta}} \frac{1}{\deg(F : \alpha \rightarrow \beta)},$$

where $\mathcal{G}_{ij}$ is the collection of curves in $G^{-1}(\gamma_j)$ homotopic to γ_i within $\mathcal{M} \setminus \mathcal{Q}$; $\mathcal{F}_{\delta\beta}$ is the collection of curves in $F^{-1}(\beta)$ homotopic to δ within $\mathcal{L} \setminus \mathcal{P}$. We claim that,

$$\forall i, j \in \{1, \dots, k\}, \quad \forall \beta \in X_j, \quad \sum_{\delta \in X_i} a_{\delta\beta} \leq b_{ij}.$$

Assume at first $\beta = \gamma_j$. We have

$$\begin{aligned} \bigcup_{\delta \in X_i} \mathcal{F}_{\delta\gamma_j} &= \{\eta \in F^{-1}(\gamma_j), \exists \delta \in X_i \text{ such that } \eta, \delta \text{ are homotopic within } \mathcal{L} \setminus \mathcal{P}\} \\ &\subset \{\eta \in F^{-1}(\gamma_j), \exists \delta \in X_i \text{ such that } \eta, \delta \text{ are homotopic within } \mathcal{M} \setminus \mathcal{Q}\} \\ &= \{\eta \in G^{-1}(\gamma_j), \exists \delta \in X_i \text{ such that } \eta, \delta \text{ are homotopic within } \mathcal{M} \setminus \mathcal{Q}\} \\ &= \{\eta \in G^{-1}(\gamma_j), \eta, \gamma_i \text{ are homotopic within } \mathcal{M} \setminus \mathcal{Q}\} \\ &= \mathcal{G}_{ij}, \end{aligned}$$

where the inclusion is due to (a), and the second equality is due to $F^{-1}(\gamma_j) = G^{-1}(\gamma_j)$. Therefore

$$\sum_{\delta \in X_i} a_{\delta\gamma_j} = \sum_{\delta \in X_i} \sum_{\alpha \in \mathcal{F}_{\delta\gamma_j}} \frac{1}{\deg(F : \alpha \rightarrow \gamma_j)} = \sum_{\alpha \in \bigcup_{\delta \in X_i} \mathcal{F}_{\delta\gamma_j}} \frac{1}{\deg(F : \alpha \rightarrow \gamma_j)}$$

$$\leq \sum_{\alpha \in \mathcal{G}_{ij}} \frac{1}{\deg(G : \alpha \rightarrow \gamma_j)} = b_{ij}.$$

This implies the claim for $\beta = \gamma_j$.

When $\beta \neq \gamma_j$, replace γ_j by β in Γ . The replacement does not change the transition matrix D_Γ . So the claim is still true.

Applying now Corollary A.6 from linear algebra, we have $\lambda(W_X) \leq \lambda(D_\Gamma)$.

But $\lambda(D_\Gamma) < 1$ as $(G, \mathcal{Q})$ has no Thurston obstructions. Consequently $\lambda(W_T) = \lambda(W_X) < 1$. So $(F, \mathcal{P})$ has no Thurston obstructions. $\square$

5 Constant complexity under pullback

We are now searching for repelling systems with some specific properties such that on one hand we are capable to solve their problem of c-equivalence to holomorphic models, and on the other hand they appear as sub-systems of any repelling system. This leads to an important class of repelling systems: those of constant complexity. We will prove at first that every repelling system contains a sub-system that is of constant complexity. We then introduce two particular types of obstructions for this class of maps, and state our Thurston-like theorem in this setting, Theorem 5.4: a repelling system of constant complexity without these specific obstructions is c-equivalent to a holomorphic model. The proof of Theorem 5.4 will be postponed to the next sections. We conclude the present section with a proof of Theorem 3.5 using Theorem 5.4.

5.1 Definitions

Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system. Let S be an $\mathcal{L}$ -piece. We say that S is *simple* if either S is annular with $S \cap \mathcal{P} = \emptyset$, or S is disc-like with $\#S \cap \mathcal{P} \leq 1$. Otherwise we say that S is *complex*, i.e. if $\#\{\text{curves in } \partial S\} + \#(S \cap \mathcal{P}) \geq 3$.

More generally, let $E \subset \mathcal{L}$ be a bordered Riemann surface. We say that E is *simple* if E is contained in either a closed annulus A in $\mathcal{L} \setminus \mathcal{P}$; or in a closed disc D in $\mathcal{L}$, such that D contains zero or one point of $\mathcal{P}$ in its interior, and that $\partial D \cap \mathcal{P} = \emptyset$. Otherwise we say E is *complex*.

Constant complexity means roughly that under the pull-back by F , both the number and the (homotopic) shapes of the complex $\mathcal{L}$ -pieces remain stable. More precisely:

Definition 5. Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system. We say that $(F, \mathcal{P})$ is **of constant complexity**, if every complex $\mathcal{L}$ -piece S , if any, contains an $\mathcal{E}$ -piece E_S such that $E_S \cap \mathcal{P} = S \cap \mathcal{P}$ and that the components of $S \setminus E_S$ are either annular or disc-like (this implies in particular both $\mathcal{P}_F, \mathcal{P}$ are contained in K_F).

Such E_S is said to be *parallel* to S . One way to obtain a parallel subsurface of S is as follows: first thicken the boundary of S (without touching $\mathcal{P}$) to reduce S to a sub-bordered surface E' , then dig a few open holes compactly contained in $\text{interior}(E') \setminus \mathcal{P}$, the result is a bordered surface E parallel to S (see Figure 2).

For an example one may take $g(z) = z^2 - 1$. Cut off a suitable neighborhood of $\mathcal{P}_g = \{\infty, 0, -1\}$ to obtain a puzzle neighborhood $\mathcal{L}$ of the Julia set so that $g^{-1}(\mathcal{L}) \subset\subset \mathcal{L}$. In this case $\mathcal{L}$ has only one piece S , which has three boundary curves, and $E_S = g^{-1}(\mathcal{L})$ has four

boundary curves. Now $g : g^{-1}(\mathcal{L}) \rightarrow \mathcal{L}$ is a repelling system of constant complexity. For details and further examples, see §6.1.

5.2 Achieving constant complexity via restriction

Theorem 5.1. *Let $(\mathcal{B} \xrightarrow{G} \mathcal{M}, \mathcal{Q})$ be a marked postcritically finite repelling system with $\partial\mathcal{M} \neq \emptyset$. Then there are two puzzle surface neighborhoods $\mathcal{E}, \mathcal{L}$ of K_G satisfying:*

- (*) $K_G \subset \subset \mathcal{E} \subset \subset \mathcal{L} \subset \subset \mathcal{M}$, $\mathcal{E} = G^{-1}(\mathcal{L})$, $\mathcal{Q} \cap K_G = \mathcal{Q} \cap \mathcal{L}$;
- (**) *for every $\mathcal{L}$ -piece S , and for the $\mathcal{M}$ -piece S_0 containing S in the interior, and for the copy $\overline{\mathbb{C}}$ of the Riemann sphere containing S_0 (therefore S), every (disc-like) component of $\overline{\mathbb{C}} \setminus S$ contains either components of ∂S_0 or points of $\mathcal{Q}$ (or both);*
- (***) *the sub-repelling system $F = G|_{\mathcal{E}} : \mathcal{E} \rightarrow \mathcal{L}$, marked by $\mathcal{Q} \cap K_G$, is of constant complexity.*

To prove the theorem, we need the following process together with its two properties:

Hole-filled-in process. Let S_0 be an $\mathcal{M}$ -piece. It is contained in a Riemann sphere $\overline{\mathbb{C}}$. Let $E \subset S_0$ be a bordered Riemann surface. The *filled-in* of E , denote by $\widehat{E}$, is defined to be the union of E with all components of $E^c = \overline{\mathbb{C}} \setminus E$ disjoint from $\partial S_0 \cup \mathcal{Q}$. Clearly, $\widehat{E} \subset S_0$ and $\partial \widehat{E} \subset \partial E$.

Monotonicity Property. Let $E_1 \subset \subset E_2$ be two nested bordered connected surfaces in $\mathcal{M}$. Then $\widehat{E}_1 \subset \subset \widehat{E}_2$.

Proof. This property is easier to understand from their complements. There is an $\mathcal{M}$ -piece S_0 containing both E_1 and E_2 . Note that E_2^c is a disjoint union of discs while $(\widehat{E}_2)^c$ is the union of some of them which meet $\partial S_0 \cup \mathcal{Q}$. Because $E_1^c \supset \supset E_2^c$, these discs are compactly contained in E_1^c , which can not be thrown away under filled-in process of E_1 since they meet $\partial S_0 \cup \mathcal{Q}$. So $(\widehat{E}_1)^c \supset \supset (\widehat{E}_2)^c$ and hence $\widehat{E}_1 \subset \subset \widehat{E}_2$.

Pull-back property. Let $S \subset \mathcal{M}$ be a bordered Riemann surface with $\partial S \cap \mathcal{Q} = \emptyset$, and let E_1 be a component of $G^{-1}(S)$. Let $\tilde{E}_1$ be the component of $G^{-1}(\widehat{S})$ containing E_1 . Then E_1 is again a bordered Riemann surface, and $\tilde{E}_1 \subset \widehat{E}_1$. See the following diagram:

$$\begin{array}{ccc} \Lambda_0 \subset \widehat{S} & \xrightarrow{\text{fill}} & S \\ G \uparrow & & \uparrow G \\ \Lambda_1 \subset \widehat{E}_1 = \text{fill}(E_1) & \xrightarrow{\text{conclusion}} & \tilde{E}_1 \supset E_1 \end{array}$$

Proof. Let Λ_0 be the $\mathcal{M}$ -piece containing S and Λ_1 be the $\mathcal{M}$ -piece containing E_1 . Assume $\Lambda_0 \subset \subset \overline{\mathbb{C}}_0$ and $\Lambda_1 \subset \subset \overline{\mathbb{C}}_1$. Denote by $\tilde{E}_i$ ($1 \leq i \leq k$) the components of $G^{-1}(\widehat{S})$. Noticing that $\widehat{S} \setminus S$ is a union of disjoint open discs, is contained in Λ_0 and is disjoint from $\mathcal{Q}$. Set $V = G^{-1}(\widehat{S}) \setminus G^{-1}(S) = G^{-1}(\widehat{S} \setminus S)$. Then V is also a disjoint union of discs and $\overline{V} \cap (\partial\mathcal{M} \cup \mathcal{Q}) = \emptyset$ (by the Basic pull-back principle). These discs are contained in $G^{-1}(\widehat{S}) = \cup \tilde{E}_i$ and hence can not separate any $\tilde{E}_i$, i.e. $\tilde{E}_i \setminus V$ is also connected for $1 \leq i \leq k$. Therefore $E_1 = \tilde{E}_1 \setminus V$. Note that each component of $\tilde{E}_1 \cap V$ is the union of some components of V which are discs contained in $\Lambda_1 \setminus \mathcal{Q}$. They are also components of $\Lambda_1 \setminus E_1$. By definition, $\tilde{E}_1 = E_1 \cup (\tilde{E}_1 \cap V) \subset \widehat{E}_1$.

Proof of Theorem 5.1.

Choice of N' to stabilize the postcritical set. Clearly there is an integer $N_0 \geq 0$ such that for all $n \geq N_0$, we have $L_n \cap \mathcal{Q} = K_G \cap \mathcal{Q}$, in other words every critical point of G in L_n is actually in K_G and is eventually periodic. For convenience we will choose $N' \geq \max\{1, N_0\}$.

Choice of N'' to stabilize the homotopy classes of the boundary curves. Note that $\partial L_n \cap \partial L_m = \emptyset$ if $n \neq m$. For any integer $m \geq 0$, we consider the homotopy classes within $\mathcal{M} \setminus \mathcal{Q}$ of the Jordan curves in $\bigcup_{k=0}^m \partial L_k$. The number of these homotopy classes is weakly increasing with respect to m , but is uniformly bounded from above, as $\mathcal{Q} \cup \partial \mathcal{M}$ has only finitely many connected components. There is therefore an integer $N'' \geq N'$ such that for any $n \geq N''$, every boundary curve of L_n is either null homotopic or homotopic, within $\mathcal{M} \setminus \mathcal{Q}$, to a curve in $\bigcup_{k=0}^{N''-1} \partial L_k$.

Filled-in for L_n . For any two L_n -pieces, their filled-in are either disjoint or one contains another. Let $\mathcal{L}_n$ be the union of the filled-in of all the L_n -pieces. Then each $\mathcal{L}_n$ -piece is the filled-in of an L_n -piece; for every $\mathcal{L}_n$ -piece S , each complementary component of S contains points of $\partial \mathcal{M} \cup \mathcal{Q}$ (i.e. $\mathcal{L}_n$ satisfies Property (**)). Note that the total number of $\mathcal{L}_n$ -pieces might be less than that of L_n -pieces, as some L_n -piece might be hidden in the hole of another, thus disappears in the filled-in process.

It is easy to check from the definition that if S is a G -complex L_n -piece, then $\hat{S}$ is a G -complex $\mathcal{L}_n$ -piece.

Assume that E is a component of $G^{-1}(S)$ where S is an L_n -piece. Let $\tilde{E}$ be the component of $G^{-1}(\hat{S})$ containing E . Then $\tilde{E} \subset \hat{E} \subset \mathcal{L}_n$ by the pull-back property and the monotonicity property of filled-in, as E is an L_{n+1} -piece and hence is contained in an L_n -piece. Combining with the fact that each $\mathcal{L}_n$ -piece is the filled-in of an L_n -piece, we have $G^{-1}(\mathcal{L}_n) \subset \mathcal{L}_{n+1} \subset \mathcal{L}_n$. Note that $G^{-1}(\mathcal{L}_n) \cap \mathcal{Q} = \mathcal{L}_n \cap \mathcal{Q} = K_G \cap \mathcal{Q}$ for all $n \geq N'$.

Choice of N to stabilize the number and the shape of the complex pieces. From now on we assume $n \geq N''$. We claim that for $k \geq 1$, each non-null-homotopic (within $\mathcal{M} \setminus \mathcal{Q}$) curve γ on $G^{-k}(\partial \mathcal{L}_n)$ is homotopic to a curve on $\partial \mathcal{L}_n$ within $\mathcal{M} \setminus \mathcal{Q}$. Note that $\gamma \subset G^{-k}(\partial \mathcal{L}_n) \subset G^{-k}(\partial L_n) = \partial L_{n+k}$. By the stability of the homotopy classes of boundary curves, there is an integer m with $m < N'' \leq n$ so that γ is homotopic (within $\mathcal{M} \setminus \mathcal{Q}$) to a curve β on ∂L_m . Because $L_{n+k} \subset \subset L_n \subset \subset L_m$, there exists a curve α on ∂L_n so that α separates β from γ . So α is also homotopic (within $\mathcal{M} \setminus \mathcal{Q}$) to γ . Let S be the L_n -piece containing α . The fact that α is not null-homotopic implies that $\hat{S}$ is a $\mathcal{L}_n$ -piece and $\alpha \subset \partial \hat{S}$. The claim is proved.

Let S be a G -complex $\mathcal{L}_n$ -piece. Assume that E_1 and E_2 are $G^{-1}(\mathcal{L}_n)$ -pieces in S and that E_1 is G -complex. Then there is a closed curve γ on ∂E_1 such that γ separates $E_1 \setminus \gamma$ from E_2 . If γ is null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$, then E_2 is simple and $E_2 \cap \mathcal{Q} = \emptyset$. Assume that γ is non-null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$. From the above claim, we have a curve α on $\partial \mathcal{L}_n$ such that α is homotopic to γ within $\mathcal{M} \setminus \mathcal{Q}$. Moreover, α can be taken on ∂S since $E_1 \subset S$. Now the closed annulus enclosed by γ and α , denote by $A(\gamma, \alpha)$, is disjoint from $\partial \mathcal{M} \cap \mathcal{Q}$. It contains either E_1 or E_2 because γ separates $E_1 \setminus \gamma$ from E_2 . Because E_1 is G -complex, we see that $E_2 \subset A(\gamma, \alpha)$ and hence E_2 is G -simple and $E_2 \cap \mathcal{Q} = \emptyset$.

The above argument shows that S contains at most one $G^{-1}(\mathcal{L}_n)$ -piece that is G -complex. In case that S contains a G -complex $G^{-1}(\mathcal{L}_n)$ -piece E_S , other $G^{-1}(\mathcal{L}_n)$ -pieces in S are simple and disjoint from $\partial \mathcal{M} \cap \mathcal{Q}$. Combining with the fact that $G^{-1}(\mathcal{L}_n) \cap \mathcal{Q} = \mathcal{L}_n \cap \mathcal{Q}$, we see that $E_S \cap \mathcal{Q} = S \cap \mathcal{Q}$.

We can show now that each component of E_S^c contains at most one component of ∂S . Let D be a component of E_S^c and $\gamma = \partial D \cap \partial E_S$. If γ is null-homotopic within $\mathcal{M} \setminus \mathcal{Q}$, then D contains no component of ∂S since each closed curve in ∂S is non-null-homotopic rel $\mathcal{Q}$. Now assume that γ is non-null-homotopic rel $\mathcal{Q}$. Then there is a curve β on ∂S homotopic to γ within $\mathcal{M} \setminus \mathcal{Q}$. Therefore the closed annulus $A(\gamma, \beta)$ bounded by γ and β is contained

in $\mathcal{M} \setminus \mathcal{Q}$.

If $\beta \subset D^c$, then $E_S \subset A(\gamma, \beta)$. This contradicts to the fact that E_S is G -complex. So $\beta \subset D$. Thus $A(\gamma, \beta) \subset S$ since S is the filled-in of an L_n -piece. Therefore no other components of ∂S is contained in D . This implies that components of $S \setminus E_S$ are either annular or disc-like.

Let s_n be the number of G -complex $\mathcal{L}_n$ -pieces. Let t_n be the number of G -complex $G^{-1}(\mathcal{L}_n)$ -pieces. Then $t_n \leq s_n$ since each G -complex $\mathcal{L}_n$ -piece contains at most one G -complex $G^{-1}(\mathcal{L}_n)$ -piece. We claim that $s_{n+1} \leq t_n$.

Let $\widehat{E}_1$ and $\widehat{E}_2$ be distinct G -complex $\mathcal{L}_{n+1}$ -pieces, where E_1 and E_2 are L_{n+1} -pieces. Then E_1 and E_2 are also G -complex by the definition. Note that $L_{n+1} \subset G^{-1}(\mathcal{L}_n) \subset \mathcal{L}_{n+1}$. We have two distinct $G^{-1}(\mathcal{L}_n)$ -pieces $\tilde{E}_1$ and $\tilde{E}_2$ such that $E_i \subset \tilde{E}_i \subset \widehat{E}_i$ ($i = 1, 2$). Again $\tilde{E}_1$ and $\tilde{E}_2$ are also G -complex. So $s_{n+1} \leq t_n$.

Now we have $s_{n+1} \leq s_n$. There is therefore an integer $N \geq N''$ such that $s_n \equiv s_N$ for $n \geq N$.

Define now a new repelling system $F : \mathcal{E} \rightarrow \mathcal{L}$ to be $G|_{G^{-1}(\mathcal{L}_N)} : G^{-1}(\mathcal{L}_N) \rightarrow \mathcal{L}_N$. It is postcritically finite with $\mathcal{P}_F = \mathcal{P}_G \cap K_G \subset \mathcal{Q} \cap K_G$, and $K_F = K_G$. Furthermore $(F, \mathcal{Q} \cap K_G)$ is of constant complexity. $\square$

5.3 Boundary curves and complex pieces

We now turn to the study of properties of constant complexity maps.

Lemma 5.2. *Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system of constant complexity.*

1. *For any $n \geq 0$, any curve in $F^{-n}(\partial \mathcal{L})$ is either null-homotopic or homotopic to a curve in $\partial \mathcal{L}$ within $\mathcal{L} \setminus \mathcal{P}$.*
2. *For any complex $\mathcal{L}$ -piece S , there is a unique $\mathcal{E}$ -piece E_S parallel to S , and $F(E_S) =: S'$ is again a complex $\mathcal{L}$ -piece.*
3. *$F_* : S_1 \rightarrow S_2$ if $F(E_{S_1}) = S_2$ is a well defined map from the set of complex $\mathcal{L}$ -pieces into itself. Every such $\mathcal{L}$ -piece is eventually periodic under F_* .*
4. *For any complex $\mathcal{L}$ -piece S and any integer $m \geq 1$, there is a unique $F^{-m}(\mathcal{L})$ -piece E in S parallel to S . Moreover, $F^m(E)$ is again a complex $\mathcal{L}$ -piece.*

Before proving it we will decompose $\mathcal{L}$ following its topology and its intersecting property with $\mathcal{P}$. Let S be a $\mathcal{L}$ -piece. We say that S is of $\mathcal{A}$ -type if $S \cap \mathcal{P} = \emptyset$ and S has exactly two boundary curves; is of $\mathcal{O}$ -type if $S \cap \mathcal{P} = \emptyset$ and S has exactly one boundary curve; is of $\mathcal{R}$ -type if $S \cap \mathcal{P}$ is a single point and S has exactly one boundary curve; is of $\mathcal{C}$ -type if $\#(S \cap \mathcal{P}) + \#\{\text{boundary curves}\} \geq 3$ (see table (4)). Note that an $\mathcal{L}$ -piece is complex iff it is a $\mathcal{C}$ -piece.

We now decompose $\mathcal{L}$ into $\mathcal{C} \sqcup \mathcal{R} \sqcup \mathcal{A} \sqcup \mathcal{O}$ with $\mathcal{C}$ the union of $\mathcal{C}$ -type pieces, $\mathcal{R}$ the union of $\mathcal{R}$ -type pieces, $\mathcal{A}$ the union of $\mathcal{A}$ -type pieces and $\mathcal{O}$ the union of $\mathcal{O}$ -type pieces. It may happen that some sets among $\mathcal{O}, \mathcal{A}, \mathcal{R}, \mathcal{C}$ are empty. See examples in §6.1.

Classification of $\mathcal{L}$ -pieces S

$\cap \mathcal{P} \backslash \text{shape}$	1 boundary curve (disc)	2 boundary curves (annulus)	≥ 3 boundary curves (pants, pillowcase without corners, etc.)
$S \cap \mathcal{P} = \emptyset$ $\gamma \subset \partial S$ is	$\mathcal{O}$ -type null-homotopic	$\mathcal{A}$ -type non-peripheral $\partial S = \partial_- S \sqcup \partial_+ S$	$\mathcal{C}$ -type non-peripheral
$S \cap \mathcal{P} \neq \emptyset$ $\gamma \subset \partial S$ is	$\#S \cap \mathcal{P} = 1$ $\mathcal{R}$ -type peripheral	$\#S \cap \mathcal{P} > 1$ $\mathcal{C}$ -type non-periph.	$\mathcal{C}$ -type non-peripheral

(4)

Proof of Lemma 5.2. (1). Due to the basic pull-back principle we just need to prove it for $n = 1$. Let γ be a boundary curve of $\mathcal{L}$. Then γ is a boundary curve of some $\mathcal{L}$ -piece S .

If S is of $\mathcal{O}$ -type, then all components of $F^{-1}(S)$ are discs in $\mathcal{L}$ and are disjoint from $\mathcal{P}$. Therefore all curves in $F^{-1}(\gamma)$ are null-homotopic.

Recall that by the definition of constant complexity, each $\mathcal{C}$ -piece S' contains a unique complex $\mathcal{E}$ -piece $E_{S'}$ and $E_{S'}$ is parallel to S' .

If S is of $\mathcal{A}$ -type or $\mathcal{R}$ -type, then each component E of $F^{-1}(S)$ is contained in

$$\mathcal{O} \sqcup \mathcal{A} \sqcup \mathcal{R} \sqcup \bigcup_{S': \mathcal{C}\text{-piece}} S' \setminus E_{S'}. \quad (5)$$

But each component of $S' \setminus E_{S'}$ for a $\mathcal{C}$ -piece S' is either an annulus or a disc, and is contained in $\mathcal{L} \setminus \mathcal{P}$. So each boundary curve of E , in particular each curve of $F^{-1}(\gamma)$, is either null-homotopic or homotopic to a curve in $\partial \mathcal{L}$.

Finally if S is of $\mathcal{C}$ -type, then a component E of $F^{-1}(S)$ is either equal to $E_{S'}$ for some $\mathcal{C}$ -piece S' , or is contained in (5). In any case each boundary curve of each of E , in particular each curve of $F^{-1}(\gamma)$, is either null-homotopic or homotopic to a curve in $\partial \mathcal{L}$.

(2). The existence of E_S is given by the definition of constant complexity. Its uniqueness follows from the fact that components of $S \setminus E_S$ are annular or disc-like and are disjoint from $\mathcal{P}$. We know that $S' := F(E_S)$ is again an $\mathcal{L}$ -piece. It must be also a $\mathcal{C}$ -piece since each component of the F -preimage of a simple $\mathcal{L}$ -piece is also simple.

(3). Clearly F_* is well defined due to (2). Since the number of $\mathcal{C}$ -pieces are finite, each of them is eventually periodic under F_* .

(4). Let S be a $\mathcal{C}$ -piece. We have seen from (3) that $S' := F(E_S)$ is again a $\mathcal{C}$ -piece. By definition of constant complexity, we know that $S' = E_{S'} \sqcup (\sqcup_i A_i \sqcup_j D_j)$, with A_i annuli and D_j discs, and that $(\sqcup_i A_i \sqcup_j D_j) \cap \mathcal{P} = \emptyset$, and that one component of ∂A_i is contained in $\partial S'$.

There are no complex $F^{-2}(\mathcal{L})$ -pieces in $\sqcup_i A_i \sqcup_j D_j$. By the basic pull-back principle, $E_S^2 := E_S \cap F^{-1}(E_{S'})$ is connected. It is reduced from E_S after thickening the boundary and then cutting off a few disjoint holes (without touching $\mathcal{P} \cap E_S$). This implies that E_S^2 is parallel to S . So E_S^2 is complex. Clearly, there is no other complex $F^{-2}(\mathcal{L})$ -piece in E_S .

Inductively, for any integer $m \geq 1$, there is a unique complex $F^{-m}(\mathcal{L})$ -piece E_S^m in S and E_S^m is parallel to S . Moreover, $F^m(E_S^m)$ is again a $\mathcal{C}$ -piece. $\square$

5.4 The boundary multicurve

Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked repelling system.

We consider now the boundary curves γ of $\mathcal{L}$ that are non-peripheral (within $\mathcal{L} \setminus \mathcal{P}$) (i.e. either γ is the boundary of a disc piece D , with $\#D \cap \mathcal{P} \geq 2$, or γ is a boundary curve of a non-disc piece). This set might be empty, or some of the curves might be homotopic to each other (for example the two boundary curves of an annular component of $\mathcal{L} \setminus \mathcal{P}$). In any case we give the

Definition 6. A *boundary multicurve* Y of $(F, \mathcal{P})$ is a collection of curves in $\partial\mathcal{L}$ representing all the homotopy classes within $\mathcal{L} \setminus \mathcal{P}$ of the non-peripheral curves in $\partial\mathcal{L}$.

Then *boundary transition matrix* $W_Y = (a_{ij})$ is defined by

$$a_{ij} = \sum_{\alpha} \frac{1}{\deg(F : \alpha \rightarrow \gamma_j)}, \quad (6)$$

where the sum is taken over all the Jordan curves (if any) of $\alpha \subset F^{-1}(\gamma_j)$ that are homotopic to γ_i (within $\mathcal{L} \setminus \mathcal{P}$).

We will say that $(F, \mathcal{P})$ has a **boundary obstruction** if $Y \neq \emptyset$ and $\lambda(W_Y) \geq 1$.

In general Y is not $(F, \mathcal{P})$ -stable, or even worse, we might have $Y \neq \emptyset$ and W_Y equal to the zero matrix.

Assume from now on that $(F, \mathcal{P})$ is also of constant complexity. Then Y is $(F, \mathcal{P})$ -stable by Lemma 5.2. It can be described more explicitly using the above classification of $\mathcal{L}$ -pieces:

A closed curve in $\partial\mathcal{L}$ is null-homotopic iff it is contained in $\partial\mathcal{O}$, is peripheral iff it is contained in $\partial\mathcal{R}$. Two closed curves in $\partial\mathcal{L}$ are homotopic iff they are the boundary curves of an $\mathcal{A}$ -piece. Label by $+$ and $-$ the two boundary curves for each $\mathcal{A}$ -piece S , i.e. $\partial S = \partial_+ S \sqcup \partial_- S$. Let $\partial_+ \mathcal{A}$ and $\partial_- \mathcal{A}$ denote the union of the corresponding boundary curves of every $\mathcal{A}$ -pieces. Then the boundary multicurve Y can be taken to be the collection of closed curves in $\partial\mathcal{C} \cup \partial_+ \mathcal{A}$.

Polynomials with all critical points escaping to ∞ provide examples, when restricted to a suitable neighborhood of the Julia set, of repelling systems with $Y = \emptyset$. For an annuli covering $F : \mathcal{E} \rightarrow \mathcal{A}$ with $\mathcal{A} = A_1 \sqcup \cdots \sqcup A_k$ (see Lemma 3.1), the set Y consists of k boundary curves of $\mathcal{A}$, one in each A_i , and the $(F, \mathcal{P})$ -transition matrix W_Y coincides with the transition matrix D defined in §3.1. For further examples see §6.1.

5.5 Renormalizations and renormalized obstructions

A repelling system of constant complexity has another, somewhat more important property: it admits renormalizations and they behave like postcritically finite branched coverings of $\overline{\mathbb{C}}$.

Definition 7. A marked postcritically finite repelling system $(E \xrightarrow{H} S, \tilde{\mathcal{P}})$ of constant complexity is of *Thurston type* if both E and S are connected, and

$$\#(S \cap \tilde{\mathcal{P}}) + \#\{\text{boundary curves of } S\} \geq 3.$$

In other words, $S, E \subset \overline{\mathbb{C}}$ are quasi-circle bordered Riemann surfaces, E is compactly contained in the interior of S , the components of $S \setminus E$ are either annular or disc-like, $H : E \rightarrow S$ is an orientation preserving branched covering, with a finite (or empty) postcritical set $\mathcal{P}_H$ which is contained in E , the set $\tilde{\mathcal{P}} \subset E$ is a finite (or empty) set containing both $H(\tilde{\mathcal{P}})$ and $\mathcal{P}_H$, and $\#(S \cap \tilde{\mathcal{P}}) + \#\{\text{boundary curves of } S\} \geq 3$.

Again, an example can be provided by the map $g(z) = z^2 - 1$, with S equal to $\overline{\mathbb{C}}$ minus a suitable neighborhood of $\infty, 0, -1$, and with $E = g^{-1}(S)$.

Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system of constant complexity. Assume $\mathcal{C} \neq \emptyset$. By Lemma 5.2, we have a map F_* defined on the collection of $\mathcal{C}$ -pieces by $F_*(S_1) = S_2$ if $F(E_{S_1}) = S_2$ where E_{S_1} is the unique $\mathcal{E}$ -piece in S_1 parallel to S_1 . Assume that S is an $\mathcal{C}$ -piece that is p -periodic under F_* . Let E be the unique $F^{-p}(\mathcal{L})$ -piece in S parallel to S . Then $F^p(E) = S$. Denote $H = F^p|_E$. Then $H : E \rightarrow S$ is a repelling system satisfying that $\mathcal{P}_H \subset \mathcal{P}_F \cap S \subset \mathcal{P} \cap S$, and that, marked by $\mathcal{P} \cap S$, the marked system $(H, \mathcal{P} \cap S)$ is of Thurston type.

Definition 8. We will call the marked repelling system $(E \xrightarrow{H} S, \mathcal{P} \cap S)$ a **renormalization** of $(F, \mathcal{P})$. We say that $(F, \mathcal{P})$ has a **renormalized obstruction** if it has a renormalization $(E \xrightarrow{H} S, \mathcal{P} \cap S)$ that has a Thurston obstruction.

Lemma 5.3. *Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system of constant complexity. If $(F, \mathcal{P})$ has no Thurston obstructions, then it has no boundary obstructions nor renormalized obstructions.*

Proof. As $(F, \mathcal{P})$ has no Thurston obstructions, we have $\lambda(W_T) < 1$ for the transition matrix W_T of every multicurve T in $\mathcal{L} \setminus \mathcal{P}$, in particular for T equal to the boundary multicurve. Therefore $(F, \mathcal{P})$ has no boundary obstructions.

It remains to show that any renormalization $H : E \rightarrow S$ marked by $\tilde{\mathcal{P}} := \mathcal{P} \cap S$ has no Thurston obstructions. Assume by contradiction that $\lambda(W_\Gamma) \geq 1$, for some $(H, \tilde{\mathcal{P}})$ -stable multicurve Γ , with $(H, \tilde{\mathcal{P}})$ -transition matrix W_Γ .

Let $S_0(= S), S_1, \dots, S_{p-1}$ be the F_* -periodic cycle of S . Let E_i be the unique $\mathcal{E}$ -piece in S_i parallel to S_i , $i = 0, 1, \dots, p-1$. Set $\Gamma_p := \Gamma$. Define inductively, for $i = p-1, p-2, \dots, 0$, the multicurve $\Gamma_i \subset F^{-1}(\Gamma_{i+1}) \cap E_i$ representing the homotopy classes (within $S_i \setminus \mathcal{P}$) of the non-peripheral curves in $F^{-1}(\Gamma_{i+1}) \cap E_i$. By stability of Γ , each curve of Γ_0 is homotopic to a curve in Γ_p .

Consider $F' : \bigcup_i E_i \rightarrow \bigcup_i S_i$ as a repelling system. Set $\Gamma' = \Gamma_1 \cup \dots \cup \Gamma_p$. It is a multicurve within $\bigcup_i S_i \setminus \mathcal{P}$, therefore within $\mathcal{L} \setminus \mathcal{P}$. Denote by $W_{\Gamma'}$ its $(F, \mathcal{P})$ -transition matrix and by W' its $(F', \mathcal{P})$ -transition matrix. Then the p -th power $(W')^p$ restricted to Γ_p is equal to W_Γ . Therefore

$$1 \leq \lambda(W_\Gamma) \leq \lambda((W')^p) = \lambda(W')^p.$$

But each entry of W' is less than or equal to the corresponding entry of $W_{\Gamma'}$. Therefore $\lambda(W') \leq \lambda(W_{\Gamma'})$. This implies that $\lambda(W_\Gamma) \geq 1$. This contradicts the assumption that $(F, \mathcal{P})$ has no Thurston obstructions (by Lemma 4.2). $\square$

We can now state our Thurston-like result in this setting, whose proof will occupy Sections 6-8:

Theorem 5.4. *Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system of constant complexity. Assume that $(F, \mathcal{P})$ has no boundary obstructions nor renormalized obstructions. Then $(F, \mathcal{P})$ is c -equivalent to a holomorphic model.*

5.6 Proof of Theorem 3.5 using Theorems 5.4

Proof of Theorem 3.5. Let $(\mathcal{B} \xrightarrow{G} \mathcal{M}, \mathcal{Q})$ be a marked postcritically finite repelling system

without Thurston obstructions. We will prove that $(G, \mathcal{Q})$ is c-equivalent to a holomorphic model.

As first we apply Theorem 5.1 to $(G, \mathcal{Q})$ to show that it has a postcritically finite repelling system restriction $F : \mathcal{E} \rightarrow \mathcal{L}$ near K_G which, marked by $\mathcal{P} := \mathcal{Q} \cap K_G$, is of constant complexity, and satisfies the conditions in Theorem 4.1. So we may apply Theorem 4.1.(B) to show that $(F, \mathcal{P})$ has no Thurston obstructions. Lemma 5.3 then leads $(F, \mathcal{P})$ to the setting of Theorem 5.4, i.e. $(F, \mathcal{P})$ is of constant complexity, and has no boundary obstructions nor renormalized obstructions. Now we may apply Theorem 5.4 to conclude that $(F, \mathcal{P})$ is c-equivalent to a holomorphic model. Finally we conclude for $(G, \mathcal{Q})$ using Theorem 4.1.(A). $\square$

Note that it could be more difficult to check the condition of Theorem 1.1 and Theorem 3.5, namely G has no Thurston obstructions. Whereas Theorem 5.4 turns it into the problem of checking the leading eigenvalue of W_Y for a single multicurve Y , and then the absence of Thurston obstructions for postcritically finite branched coverings (arising from the renormalizations), to which there is a huge literature (see for example the references in [ST]). This form is particularly suitable for combination of rational maps, i.e. starting with postcritically finite rational maps (thus already holomorphic) as the renormalizations and glue them suitably together.

6 C-equivalence to holomorphic models

From now on we concentrate on the proof of Theorem 5.4: a marked postcritically finite repelling system of constant complexity without boundary obstructions nor renormalized obstructions is c-equivalent to a holomorphic model. In this section we will prove the theorem for the non-renormalizable case. In this case only Grötzsch inequalities are needed, but not the original Thurston theorem.

Recall that from Definition 4 and Lemma 2.3 that a marked repelling system $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ is c-equivalent to a holomorphic model, if there is a marked repelling system $(\mathcal{E}' \xrightarrow{R} \mathcal{L}', \mathcal{P}')$ with R holomorphic, and two quasi-conformal homeomorphisms $\Theta : \mathcal{L} \rightarrow \mathcal{L}'$, $\Phi : \mathcal{L} \rightarrow \mathcal{L}'$ with

$$\begin{cases} \Phi \circ \Theta(\mathcal{E}) = \mathcal{E}', \quad \Phi \circ \Theta(\mathcal{P}) = \mathcal{P}' \\ R \circ \Phi \circ \Theta|_{\mathcal{E}} = \Phi \circ F \\ \Theta \text{ is isotopic to the identity rel } \mathcal{P} \cup \partial \mathcal{L}. \end{cases}$$

6.1 Examples

$\mathcal{L} = Q$, $\mathcal{E} = E_1 \cup E_2$, with Q, E_1, E_2 quasi discs.
 $F : E_i \rightarrow Q$ are quasi-conformal homeomorphisms
 $\mathcal{P} = \emptyset$.

Lemma 6.1. *The map F in Example 1 is always c -equivalent to a holomorphic model, whereas in Example 2 it is so if and only if $\frac{1}{d_1} + \frac{1}{d_2} < 1$.*

Proof. Let $F : E_1 \cup E_2 \rightarrow Q$ be as in Example 1.

1. Construct at first the model map R by setting $E'_i = E_i$, $Q' = Q$ and by choosing $R : E'_i \rightarrow Q'$ any conformal homeomorphism.
2. Set $\Phi = id : Q \rightarrow Q$.
3. Set $\begin{cases} \theta|_{E_i} &= R^{-1} \circ F \\ \theta|_{\partial Q} &= id. \end{cases}$ Then $R \circ \Phi \circ \theta|_{E_i} = \Phi \circ F$.
4. Extend θ as a homeomorphism of Q .
5. One checks easily that this θ is isotopic to the identity rel ∂Q .

Let now $F : A_1 \cup A_2 \rightarrow A$ be a map in Example 2. Note that A has a unique multicurve Γ , up to homotopy, with Γ consisting of a boundary curve of A . Its F -transition matrix has only one entry, which is $\frac{1}{d_1} + \frac{1}{d_2}$. Therefore F has a Thurston obstruction if and only if $\frac{1}{d_1} + \frac{1}{d_2} \geq 1$.

If F is c -equivalent to a holomorphic $R : A'_1 \cup A'_2 \rightarrow A'$. Then by Grötzsch inequality $\frac{1}{d_1} + \frac{1}{d_2} < 1$.

Conversely assume $\frac{1}{d_1} + \frac{1}{d_2} < 1$.

- a. Construct at first a round modulus A' of modulus, say v . And let $\Phi : A \rightarrow A'$ be a qc-homeomorphism.
- b. Construct then two disjoint essential round submoduli A'_1, A'_2 in A' of moduli v/d_1 and v/d_2 respectively, and displaced in the same order as the A_i 's in A . This is possible precisely because $\sum \frac{1}{d_i} < 1$. Choose $R : A'_i \rightarrow A'$ a holomorphic covering of degree d_i , matching the boundary correspondence as F .
- c. Pull-back A'_i by Φ

- d. Set $\begin{cases} \theta|_{A_i} : &= (\Phi^{-1} \circ R \circ \Phi)^{-1} \circ F : A_i \longrightarrow \Phi^{-1}(A_i) \\ \theta|_{\partial A} &= id \end{cases}$
- e. Extend θ as a qc-homeomorphism $A \rightarrow A$. Then $R \circ \Phi \circ \theta|_{A_i} = \Phi \circ F$.
- f. Via *Dehn twist* on $A \setminus (A_1 \cup A_2)$ to modify the extension so that $\theta(\beta) \sim \beta$.

This guarantees that θ is isotopic to the identity rel ∂A . $\square$

Example 3. Let L be a pair of trousers bounded by three quasi-circles $\gamma_0, \gamma_{-1}, \gamma_*$. Let $E \subset L$ be a surface bounded by four quasi-circles $\beta_0, \beta_{-1}, \beta_*, \beta_1$, with β_1 bounding a complementary disc of E that is entirely contained in L , and with each other β_i bounding a complementary disc of E that contains the corresponding γ_i . Let $H : E \rightarrow L$ be a quasi-regular covering of degree 2. Again $\mathcal{P}_H = \mathcal{P} = \emptyset$. And H is of Thurston type.

The boundary multicurve Y is simply $\{\gamma_0, \gamma_{-1}, \gamma_*\}$. For example if we require $H : \beta_* \rightarrow \gamma_*$ to be degree 2, $H : \beta_{\pm 1} \rightarrow \gamma_0$ of degree 1 and $H : \beta_0 \rightarrow \gamma_{-1}$ of degree 2, then the transition matrix W_Y is $\begin{pmatrix} 0 & \frac{1}{2} & 0 \\ 1 & 0 & 0 \\ 0 & 0 & \frac{1}{2} \end{pmatrix}$ with leading eigenvalue $1/\sqrt{2}$. Such a map behaves like $z^2 - 1$.

On the other hand, if we require instead $H : \beta_* \rightarrow \gamma_*$ to be degree 2, $H : \beta_{\pm 1} \rightarrow \gamma_1$ of degree 1 and $H : \beta_0 \rightarrow \gamma_0$ of degree 2, then the transition matrix W_Y is $\begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \frac{1}{2} \end{pmatrix}$ with leading eigenvalue 1. This H can be constructed more explicitly as follows (suggested by X. Buff): Let $g(z) = z^2$. Let L be $\overline{\mathbb{C}}$ minus a small round disc of radius ε around each of the three points $0, \infty$ and 1 . Let $E' = g^{-1}(L)$. As 1 is a repelling fixed point of g , E' is not compactly contained in L and $g : E' \rightarrow L$ is not a repelling system. Let now $\eta : \overline{D}(1, 2\varepsilon) \rightarrow \overline{D}(1, 2\varepsilon)$ to be a homeomorphism fixing pointwisely the boundary and center, mapping the boundary component of E' into the interior of L . Extend η elsewhere by identity. Set $H = g \circ \eta^{-1} : \eta(E') \rightarrow L$.

Note that every non-peripheral curve is homotopic to one of the curves in Y . So H has a Thurston obstruction if and only if $\lambda(W_Y) \geq 1$.

Lemma 6.2. *This H is c -equivalent to a holomorphic model if and only if the H -transition matrix of $Y = \{\gamma_0, \gamma_{-1}, \gamma_*\}$ has a leading eigenvalue $\lambda < 1$.*

Proof. Mark one point in each complement component of L . Denote the marked set by $\mathcal{P}$.

Extend H as a quasi-regular branched cover $\hat{H}$ of $\bar{\mathbb{C}}$ such that the critical values are in $\mathcal{P}$ and $\hat{H}(\mathcal{P}) \subset \mathcal{P}$, and that $\hat{H}$ is holomorphic outside L . In particular $\hat{H}$ is postcritically finite.

Assume at first the H is c-equivalent to a holomorphic model. Then by Lemma 2.3 there is a quasi-conformal automorphism $\theta : L \rightarrow L$, isotopic to the identity rel ∂L , and a Beltrami differential μ supported on L with $\|\mu\|_\infty < 1$, such that $(H \circ \theta^{-1})^* \mu = \mu|_{\theta(E)}$.

Proceed now at in the proof of Proposition 2.4. Extend θ to be equal to the identity outside L . Set $\hat{H}_1 = \hat{H} \circ \theta^{-1}$. Extend μ outside L by $\mu = 0$. Let $\phi_1 : \bar{\mathbb{C}} \rightarrow \bar{\mathbb{C}}$ be a global integrating map of this extended μ . Set $\hat{H}_2 := \phi_1 \circ \hat{H}_1 \circ \phi_1^{-1}$. Then $\hat{H}_2$ is again quasi-regular, and is holomorphic in the interior of $\phi_1 \circ \theta(E)$ and in $\phi_1(L)$. Elsewhere each $\hat{H}_2$ -orbit passes at most once. We spread out the Beltrami differential $\nu_0 \equiv 0$ using iterations of $\hat{H}_2$ to get an $\hat{H}_2$ -invariant Beltrami differential ν . Note that $\nu = 0$ on $\phi_1(L)$, and $\|\nu\|_\infty < 1$. Integrating ν by a quasi-conformal homeomorphism ϕ_2 (necessarily holomorphic on $\phi_1(L)$), we get a new map $f := \phi_2 \circ \hat{H}_2 \circ \phi_2^{-1}$ which is a rational map and is c-equivalent to $\hat{H}_2$, therefore to $\hat{H}$. See the following diagram.

$$\begin{array}{ccccccc} (\bar{\mathbb{C}}, E) & \xrightarrow{\theta} & \bar{\mathbb{C}} & \xrightarrow{\phi_1} & \bar{\mathbb{C}} & \xrightarrow{\phi_2} & \bar{\mathbb{C}} \\ \hat{H} \downarrow & & \downarrow \hat{H}_1 & & \downarrow \hat{H}_2 & & \downarrow f \\ (\bar{\mathbb{C}}, L) & \xrightarrow{id} & \bar{\mathbb{C}} & \xrightarrow{\phi_1} & \bar{\mathbb{C}} & \xrightarrow{\phi_2} & \bar{\mathbb{C}} \end{array}$$

Set $\phi = \phi_2 \circ \phi_1$. Then $\phi(\partial L)$ is contained in the attracting basins of f . But f is postcritically finite, each attracting cycle must be superattracting. It follows that the boundary multicurve of the repelling system $f|_{\phi \circ \theta(E)}$ has leading eigenvalue < 1 . Therefore $\lambda(W_Y) < 1$ for our map H .

Conversely, assume that $\lambda(W_Y) < 1$ for H . The fact that $\#\mathcal{P} = 3$ implies that $(\hat{H}, \mathcal{P})$ has no Thurston obstructions. By Thurston theorem there are $\Phi = id$, Ψ homeomorphism, and f a rational map, such that $f \circ \Psi = \Phi \circ \hat{H}$, and that Ψ is isotopic to Φ rel $\mathcal{P}$.

Let v be a positive vector so that $W_Y v < v$. Change Φ within its isotopy class to ϕ so that $\phi(\gamma)$, for any $\gamma \in Y$, is an equipotential in a Fatou component Σ of f . Further, the annular component of $\Sigma \setminus \phi(\gamma)$ is of modulus $v(\gamma)$. Let ψ be the homeomorphism isotopic to Ψ so that $f \circ \psi = \phi \circ \hat{H}$. Now $W_Y v < v$ assures that $\psi(E)$ is compactly contained in $\phi(L)$.

Use Lemma D.1 to modify ψ on $L \setminus E$ so that ψ is isotopic to ϕ rel $\bar{\mathbb{C}} \setminus L$, and $f \circ \psi|_E = \phi|_L \circ H$. $\square$

Example 4. The following $F : \bigcup E_* \rightarrow S \sqcup A$ is an unbranched repelling system of constant complexity.

In this case the boundary multicurve Y consists of the three boundary curves $\gamma_1, \gamma_2, \gamma_3$ of S together with one of the two boundary curves, named by γ_4 of A . And F has only one

renormalization $(E_{SS} \xrightarrow{F} S)$.

Lemma 6.3. *If the F -transition matrix W_Y of Y has leading eigenvalue less than 1, then F is c -equivalent to a holomorphic model.*

Sketch of the proof. Let $v = (v_1, v_2, v_3, v_4)$ be a vector with each $v_i > 0$ such that $W_Y v < v$. Set $H = F|_{E_{SS}}$. Now the boundary multicurve is simply $\{\gamma_1, \gamma_2, \gamma_3\}$, the its H -transition matrix D_* is a submatrix of W_Y , therefore $D_* u < u$ for $u = (v_1, v_2, v_3)$. We may then, as in Example 3, construct ϕ, ψ making H c -equivalent to a holomorphic model f , so that $\phi(\gamma_i)$ has the potential prescribed by v_i , $i = 1, 2, 3$.

But the presence of E_{AS} requires further control of ϕ, ψ .

Fix $M > 0$ a large number. Modify again ϕ, ψ (but not f) according to the vector Mu .

Let now A' be a round annulus of modulus Mv_4 .

Fill in the hole in E_{AS} to get $\hat{E}_{AS}$ that is an essential annulus is A . Denote by α, β the boundary curves of $\hat{E}_{AS}$.

Assume, say, F maps α to γ_1 with degree d_1 , and β to γ_2 with degree d_2 . Then a candidate $\hat{E}'_{AS}$ has a modulus bounded by $\frac{Mv_1}{d_1} + \frac{Mv_2}{d_2} + C$ with a constant C independent of M (due to Lemma B.1). Choose M so that $C < M \inf_i (v_i - (W_Y v)_i)$.

Set then $E'_{SS} = f^{-1}(S') = \psi(E_{SS})$.

Now $(W_Y(Mv))_i + C < Mv_i$ guarantees that one can insert two disjoint essential annuli $\hat{E}'_{AS}, E'_{AA1}$ in A' , and insert an essential annulus E'_{SA1} in the corresponding annulus of $S' \setminus E'_{SS}$, together with a model holomorphic covering $R : E'_{*Aj} \rightarrow A', E'_{*S} \rightarrow S'$ with the same degree as F and the same boundary correspondence. Then the construction of θ is similar.

Details are provided in §8. □

6.2 A criterion for c -equivalence to holomorphic models

The following simple remark turns concept of c -equivalence into a more practical form:

Lemma 6.4. *Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system. Then $(F, \mathcal{P})$ is c -equivalent to a holomorphic model if and only if: for each $\mathcal{L}$ -piece S , there is a pair of quasi-conformal homeomorphisms $\theta_S : S \rightarrow S$, $\phi_S : S \rightarrow S' \subset \overline{\mathbb{C}_{S'}}$ (here we consider $\overline{\mathbb{C}_{S'}}$ as a distinct copy of the Riemann sphere), such that:*

- (a) θ_S is the identity on $\partial S \cup \mathcal{P}$ and is isotopic to the identity rel $\partial S \cup \mathcal{P}$.
- (b) For every $\mathcal{E}$ -piece E contained in S , and for $\hat{S} = F(E)$ (which is again an $\mathcal{L}$ -piece), the composition $R_E := \phi_{\hat{S}} \circ F \circ \theta_S^{-1} \circ \phi_S^{-1}$ is holomorphic in the interior of $\phi_S \circ \theta_S(E)$. See (7).

The proof is almost straight forward. One just need to set $\theta = \Phi^{-1} \circ \Psi$ in the definition of c -equivalence, and set $\theta_S = \theta|_S$, $\phi_S = \Phi|_S$ and $R_E = R|_{\phi_S \circ \theta_S(E)}$.

Therefore to prove that $(F, \mathcal{P})$ is c -equivalent to a holomorphic model, it amounts to construct ϕ_S, θ_S and R_E for each $\mathcal{L}$ -piece S and each $\mathcal{E}$ -piece E in S so that they satisfy (a) and (b). In practical the maps ϕ_S, R_E will be constructed first. One constructs then each $\theta_E = \theta_S|_E$, and finally glue the various θ_E 's together to get θ_S . See the following schema:

Order of the construction

$$\begin{array}{ccccc}
S & \xrightarrow[4.]{\theta_S} & S & \xrightarrow[1.]{\phi_S} & S' \subset \overline{\mathbb{C}}_{S'} \\
\cup & & \cup & & \cup \\
\forall \mathcal{E}\text{-piece } E \subset S, & E \xrightarrow[3.]{\theta_S|_E = \theta_E} \tilde{E} & \xrightarrow[2.]{\phi_S} & E' & \\
F \downarrow & & & & \downarrow \text{1. } R_E \text{ holomorphic} \\
\hat{S} & \xrightarrow{id} & \hat{S} & \xrightarrow[1.]{\phi_{\hat{S}}} & \hat{S}' \subset \overline{\mathbb{C}}_{\hat{S}'}
\end{array} \tag{7}$$

6.3 Annuli coverings

Let now $f : \mathcal{E} \rightarrow \mathcal{A}$ be an annuli covering. In other words, $\mathcal{A} = A_1 \sqcup \cdots \sqcup A_k$, $\mathcal{E} = \bigsqcup_{ij\delta} E_{ij\delta}$, with each A_i (and $E_{ij\delta}$) an annulus, and with $E_{ij\delta} \subset \subset A_i$ for $i, j \in \{1, \dots, k\}$ and δ in some finite or empty index set Λ_{ij} depending on (i, j) , and $f : E_{ij\delta} \rightarrow A_j$ is a quasi-regular covering of certain degree, denoted by $d_{ij\delta}$. Recall that the transition matrix D is defined by

$$D = (a_{ij}), \quad a_{ij} = \sum_{\delta \in \Lambda_{ij}} \frac{1}{d_{ij\delta}}.$$

We will prove the following more concrete form of Lemma 3.1:

Lemma 6.5. *For the annuli covering $f : \mathcal{E} \rightarrow \mathcal{A}$ as above, assume that there is a vector $v = (v_1, \dots, v_k)$ with $v_i > 0$ for any i such that $Dv < v$, i.e.*

$$\forall i = 1, \dots, k, \quad \sum_{j, \delta} \frac{v_j}{d_{ij\delta}} < v_i. \tag{8}$$

Then $f : \mathcal{E} \rightarrow \mathcal{A}$ is c -equivalent to a holomorphic model $R : \mathcal{E}' \rightarrow \mathcal{A}'$ with $\mathcal{A}' = A'_1 \sqcup \cdots \sqcup A'_k$ and $\text{mod}(A'_i) = v_i$.

Here the modulus of a closed annulus will mean the modulus of its interior as an open annulus. Now Lemma A.1 relates $\lambda(D) < 1$ to the existence of such vector v . And Lemma 3.1 follows.

Proof of Lemma 6.5.

We consider each A_i as embedded in a distinct copy $\overline{\mathbb{C}}_i$ of the Riemann sphere. Take one more copy $\overline{\mathbb{C}}'_i$ for each $i = 1, \dots, k$.

For each $i \in \{1, \dots, k\}$, we will construct a pair (θ_i, ϕ_i) such that (see (9)):

(a) $\theta_i : A_i \rightarrow A_i$ is a quasi-conformal map, with $\theta_i|_{\partial A_i} = id$ and with θ_i isotopic to the identity rel ∂A_i . The set $\theta_i(E_{ij\delta})$ is denoted by $\tilde{E}_{ij\delta}$ for each possible (j, δ) .

(b) $\phi_i : A_i \rightarrow A'_i$ is a quasi-conformal homeomorphism. The set $\phi_i(\tilde{E}_{ij\delta})$ is denoted by $E'_{ij\delta}$ for each possible (j, δ) .

(c) For each multi index $ij\delta$, the map $R_{ij\delta} := \phi_j \circ f \circ (\phi_i \circ \theta_i)^{-1}|_{E'_{ij\delta}}$ is holomorphic in the interior of $E'_{ij\delta}$.

$$\begin{array}{ccccc}
A_i & \xrightarrow{\theta_i} & A_i & \xrightarrow{\phi_i} & A'_i \subset \overline{\mathbb{C}}'_i \\
\cup & & \cup & & \cup \\
E_{ij\delta} & \xrightarrow{\theta_i = \theta_{ij\delta}} & \tilde{E}_{ij\delta} & \xrightarrow{\phi_i} & E'_{ij\delta} \\
\downarrow f & & & & \downarrow R_{ij\delta} \text{ holomorphic} \\
A_j & \xrightarrow{id} & A_j & \xrightarrow{\phi_j} & A'_j \subset \overline{\mathbb{C}}'_j
\end{array} \tag{9}$$

We will follow the order of construction as indicated by (7). Once this is done we can apply Lemma 6.4 to conclude that $f : \mathcal{E} \rightarrow \mathcal{A}$ is c-equivalent to a holomorphic model.

1. Definition of $(\phi_i, A'_i, E'_{ij\delta}, R_{ij\delta})$: For every $i \in \{1, \dots, k\}$, choose $A'_i \subset \overline{\mathbb{C}}'_i$ a closed round annulus of modulus v_i , and let $\phi_i : A_i \rightarrow A'_i$ be a quasi-conformal homeomorphism.

Fix an index i . For every possible choice of (j, δ) , the lower diagram of (9) indicates that $R_{ij\delta} : E'_{ij\delta} \rightarrow A'_j$ is a covering isomorphic to $\phi_j \circ f : E_{ij\delta} \rightarrow A'_j$, therefore is an annuli covering of degree $d_{ij\delta}$. But $R_{ij\delta}$ is supposed to be holomorphic and $\text{mod}(A'_j) = v_j$. This imposes that $E'_{ij\delta}$ must be a sub-annulus of A'_i with modulus $v_j/d_{ij\delta}$.

Choose now a closed round essential annulus $E'_{ij\delta}$ in A'_i such that (1) $E'_{ij\delta} \cap \partial A'_i = \emptyset$; (2) $\text{mod}(E'_{ij\delta}) = v_j/d_{ij\delta}$ and the $(E'_{ij\delta})$'s are mutually disjoint for all possible indices (j, δ) (this is possible precisely because of (8)); (3) the $(E'_{ij\delta})$'s are displaced in A'_i in the same order as the $(E_{ij\delta})$'s in A_i .

Choose now $R_{ij\delta} : E'_{ij\delta} \rightarrow A'_j$ a holomorphic covering of degree $d_{ij\delta}$ among the two round annuli, so that it permutes the boundary curves in the same way as $f : E_{ij\delta} \rightarrow A_j$.

More precisely this can be done through *boundary labeling*: for each A_i choose a labelling by $+$ and $-$ for its two boundary curves. This induces a labelling by $\pm$ on the boundary curves of each essential sub-annulus $E_{ij\delta}$, so that $\partial_- E_{ij\delta}$ separates $\partial_- A_i$ to $\partial_+ E_{ij\delta}$. Now use each ϕ_i to transport these labellings to $\partial A'_i$ which then induces a labelling on each $\partial E'_{ij\delta}$. The covering $f : E_{ij\delta} \rightarrow A_j$ maps $\partial_- E_{ij\delta}$ to one of $\partial_\pm A_j$. We choose $R_{ij\delta}$ so that it sends $\partial_- E'_{ij\delta}$ to $\phi_j(f(\partial_- E_{ij\delta}))$, the corresponding boundary component of A'_j .

2. Definition of $\tilde{E}_{ij\delta}$: For any multi-index (i, j, δ) , set $\tilde{E}_{ij\delta} := \phi_i^{-1}(E'_{ij\delta})$ (there are a priori two ways to label its boundary curves, one as an essential sub-annulus of A_i , one transported by ϕ_i^{-1} of the labeling of $\partial E'_{ij\delta}$, but these two labellings actually coincide).

3. Definition of $\theta_{ij\delta}$. For any multi-index (i, j, δ) , let $\theta_{ij\delta} : E_{ij\delta} \rightarrow \tilde{E}_{ij\delta}$ be a (choice of a) lift of the quasi-conformal map $\phi_j : A_j \rightarrow A'_j$ via the two quasi-regular coverings of the same degree: $f|_{E_{ij\delta}}$ and $R_{ij\delta} \circ \phi_i|_{\tilde{E}_{ij\delta}}$. It is a quasi-conformal map and preserves the boundary labelling.

$$\begin{array}{ccccc}
E_{ij\delta} & \xrightarrow{\theta_{ij\delta}} & \tilde{E}_{ij\delta} & \xrightarrow{\phi_i} & E'_{ij\delta} \\
f \downarrow & & & & \downarrow R_{ij\delta} \\
A_j & & \xrightarrow{\phi_j} & & A'_j
\end{array}$$

4. Definition of θ_i . Fix an index i . Define $\theta_i : A_i \rightarrow A_i$ to be a quasi-conformal map such that $\theta_i|_{E_{ij\delta}} = \theta_{ij\delta}$ and $\theta_i|_{\partial A_i} = id$. It exists always, because all the boundary curves are quasi-circles and all $\theta_{ij\delta}$ are quasi-conformal maps preserving the boundary labelling (see Lemma C.2).

The map θ_i satisfies all the required properties, except possibly the one about their homotopy type.

4'. Adjustment of the homotopy type of θ_i . As the lower commuting diagram in (9) only requires information on $\theta_{ij\delta}$, we will modify each θ_i without changing its value on the $E_{ij\delta}$'s.

Fix an index i . Choose an arc β connecting the two boundaries of A_i . Then $\theta_i(\beta)$ is again an arc in A_i with the same end points. Precompose θ_i with a quasi-conformal repeated Dehn twist supported in the interior of $A_i \setminus \bigcup_{(j,\delta)} E_{ij\delta}$ if necessary we can ensure that $\theta_i(\beta)$ is homotopic to β (rel ∂A_i). After this adjustment θ_i is well isotopic to the identity rel ∂A_i . $\square$

6.4 The non-renormalizable case

Proof of Theorem 5.4 in case $\mathcal{C} = \mathcal{R} = \emptyset$ and $\mathcal{P} = \emptyset$.

Let $F : \mathcal{E} \rightarrow \mathcal{L}$ be a repelling system. Assume that $\mathcal{P}_F = \mathcal{P} = \emptyset$ and that every $\mathcal{L}$ -piece is either annular or disc-like. Then F is of constant complexity and there is nothing to renormalize. Furthermore the boundary multicurve Y is simply the collection of one boundary curve in each annular piece of $\mathcal{L}$. Assume now $\lambda(W_Y) < 1$. We want to prove that $F : \mathcal{E} \rightarrow \mathcal{L}$ is c -equivalent to a holomorphic model. Set

$$\mathcal{L} = \mathcal{A} \sqcup \mathcal{O}, \quad \mathcal{A} = A_1 \sqcup \cdots \sqcup A_k, \quad \mathcal{O} = O_{k+1} \sqcup \cdots \sqcup O_m$$

so that each A_i is annular and each O_j is disc-like.

0. The vector v . Choose a vector $v \in \mathbb{R}^k$ with every entry positive such that $W_Y(v) < v$.

1. Definition of (ϕ_S, S', E', R_E) . Consider each $\mathcal{A} \sqcup \mathcal{O}$ -piece S as a subset of a distinct copy $\overline{\mathbb{C}}_S$ of the Riemann sphere. If $S = A_i$, define as above $\phi_S : S \rightarrow S'$ to be a quasi-conformal homeomorphism so that S' is a round annulus with modulus v_i . If $S = O_i$, set simply $\phi_S = id$ and $S' = S$.

For any $\mathcal{E}$ -piece E , there are two $\mathcal{A} \sqcup \mathcal{O}$ -pieces S and $\hat{S}$ (possibly the same) such that $E \subset\subset S$ and $F(E) = \hat{S}$. As F is a covering, we know that E is an annulus (resp. disc) if and only if $\hat{S}$ is an annulus (resp. disc).

We decompose $\mathcal{E}$ into $\mathcal{E}^{\mathcal{A}} \sqcup \mathcal{E}^{0,\mathcal{A}} \sqcup \mathcal{E}^{0,0}$ as follows:

- $\mathcal{E}^{\mathcal{A}}$ consists of $\mathcal{E}$ -pieces that are essential sub-annuli in $\mathcal{A}$. We numerate as above these pieces by $E_{ij\delta}$ so that $E_{ij\delta} \subset A_i$ and $F(E_{ij\delta}) = A_j$. Label by $\pm$ the boundary curves of each A_i , give each $\partial E_{ij\delta}$ the induced labelling.

- $\mathcal{E}^{0,\mathcal{A}}$ consists of the remaining annular $\mathcal{E}$ -pieces. Such a piece E is a closed annulus contained in some $\mathcal{L}$ -piece S , with either $S = O_i$ or $S = A_i$. In the latter case E is contained in a component B of $S \setminus \bigcup_{(j,\delta)} E_{ij\delta}$, and E is non-essential in B . See Figure 2. In any case both boundary curves of E are F -null-homotopic. Furthermore E has one complementary component Δ_E that is entirely contained in S . We will call Δ_E the hole of E . We will label ∂E so that $\partial_- E = \partial \Delta_E$. Therefore $\partial_+ E$ denotes the outer boundary of E .

- Finally $\mathcal{E}^0$ consists of the disc pieces of $\mathcal{E}$. Such a piece E may be contained in $\mathcal{A}$ or in $\mathcal{O}$, but $F(E)$ is always an $\mathcal{O}$ -piece, and $F : E \rightarrow F(E)$ is a homeomorphism.

The general strategy is quite simple to explain: we should at first construct (E', R_E) for all the $\mathcal{E}^{\mathcal{A}}$ -pieces as in Lemma 6.5. For the remaining $\mathcal{E}$ -pieces, as they may be nested in each others holes, we should construct (E', R_E) inductively from outer pieces to inner pieces.

1.1. Construction of (E', R_E) for each $\mathcal{E}^{\mathcal{A}}$ -piece E . For all possible (i, j, δ) , define $E'_{ij\delta}$ to be a round annulus in A'_i exactly as in the proof of Lemma 6.5 above, in particular the various $E'_{ij\delta}$ for a given i are displaced in A'_i exactly in the same order as the $E_{ij\delta}$'s in A_i

and $\deg(F : E'_{ij\delta}) = v_j / \deg(F : E_{ij\delta} \rightarrow A_j)$. This is where we have used the assumption $\lambda(W_Y) < 1$. Let $R_{ij\delta} : E'_{ij\delta} \rightarrow A'_j$ be a holomorphic covering of degree $\deg(F : E_{ij\delta} \rightarrow A_j)$, and permuting the boundary labelling in the same way as $F : E_{ij\delta} \rightarrow A_j$.

1.2. Construction of (E', R_E) for each $\mathcal{E}^{0,\mathcal{A}}$ -piece E . Let now E be an $\mathcal{E}^{0,\mathcal{A}}$ -piece. Then E is contained in a set B which is either some O_i or one component of $A_i \setminus \bigcup_{(j,\delta)} E_{ij\delta}$ for some A_i . Furthermore F maps E onto some A_j as a covering. Denote its degree by d_E . Denote by B' the corresponding O'_i or the corresponding component of $A'_i \setminus \bigcup_{j\delta} E'_{ij\delta}$. We want to set E' to be an inessential annulus in B' with modulus v_j/d_E , so that there is a holomorphic covering $R_E : E' \rightarrow A'_j$ of degree d_E .

However one might run into some moduli difficulty if we do so randomly, as various pieces of $\mathcal{E}^{0,\mathcal{A}}$ in B may be nested in each others holes. The correct way to do this is to place E' one by one from outside to inside. More precisely, numerate the $\mathcal{E}^{0,\mathcal{A}}$ -pieces in B by $E_{Bj\delta}$, with δ running in some index set (depending on j) such that $F(E_{Bj\delta}) = A_j$ and it is a covering of degree $d_{Bj\delta}$. Define then a layer (depth) function $l(E)$ on the set of $(E_{Bj\delta})_{j\delta}$ as follows: set $l(E) = 1$ if E is outermost, i.e. not contained in the hole of any other $\mathcal{E}^{0,\mathcal{A}}$ -pieces. Set inductively $l(E) = m$ if E is contained immediately in the hole of a $E_{Bj\delta}$ with $l(E_{Bj\delta}) = m - 1$.

Start now with an $E_{Bj\delta}$ so that $l(E_{Bj\delta}) = 1$. Choose $E'_{Bj\delta} \subset\subset B'$ to be any round inessential annulus of modulus $v_j/d_{Bj\delta}$. Label its outer boundary curve by $+$. Choose then $R_{Bj\delta} : E'_{Bj\delta} \rightarrow A'_j$ a holomorphic covering of degree $d_{Bj\delta}$, so that it permutes the boundary labelling in the same way as $F : E_{Bj\delta} \rightarrow A_j$.

Construct similarly (E', R_E) for every layer 1 piece in B , and be sure that the various E' 's are mutually disjoint.

Now we should construct (E', R_E) for the next layer $\mathcal{E}^{0,\mathcal{A}}$ -pieces in B . Proceed this layer by layer. As each time we are supposed to find finitely many disjoint annuli non mutually nested of prescribed moduli in the hole of some previously constructed E' , the construction is always realizable.

Do this construction for every component B of $\mathcal{L} \setminus \mathcal{E}^{\mathcal{A}}$.

1.3. Construction of (E', R_E) for each $\mathcal{E}^0$ -piece E . Assume $E \subset S$ and $F(E) = \widehat{S}$. We should choose a closed quasi-disc E' in S' disjoint from the previously constructed pieces, together with a conformal map $R_E : E' \rightarrow \widehat{S}'$. There is no difficulty here and we omit the details.

To recapitulate we may extend the layer function $l(E)$ on all $\mathcal{E}$ -pieces so that $l(E) = 0$ for $\mathcal{E}^{\mathcal{A}}$ -pieces and $l(E) = +\infty$ for $\mathcal{E}^0$ -pieces, and then construct (E', R_E) following the natural order of the layer function.

2-3. Definition of $(\widetilde{E}, \theta_E)$. This is done exactly as in Lemma 6.5, by setting $\widetilde{E} = \phi_S^{-1}(E')$ for S the $\mathcal{L}$ -piece containing E , and $\theta_E : E \rightarrow \widetilde{E}$ as a lift of $\phi_{\widehat{S}} : \widehat{S} \rightarrow \widehat{S}'$ via $F|_E$ and $R_E \circ \phi_S|_{\widetilde{E}}$, where $\widehat{S} = F(E)$.

4. Definition of θ_S . Fix an $\mathcal{L}$ -piece S . We claim that we can define a quasi-conformal map $\theta_S : S \rightarrow S$ so that $\theta_S = \theta_E$ on each $\mathcal{E}$ -piece E contained in S and $\theta_S = id$ on ∂S . Clearly the extension can be chosen so that θ_S is a homeomorphism, as the θ_E 's for all possible E preserve the boundary labelling. But all the boundary curves are quasi-circles and all the θ_E 's are quasi-conformal. One can then apply Lemma C.2 to make the extension quasi-conformal.

4'. Adjustment of the homotopy type of θ_{A_i} . Clearly θ_S for S an $\mathcal{O}$ -piece is already isotopic to the identity rel ∂S . However for S an $\mathcal{A}$ -piece one might have to precompose θ

with a repeated Dehn twist supported on the interior of $S \setminus \mathcal{E}$ as in Lemma 6.5. After that θ_S is also isotopic to the identity rel ∂S . $\square$

7 Holomorphic model of a renormalization cycle

Let $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked postcritically finite repelling system of constant complexity without boundary obstructions nor renormalized obstructions. We will prove here that a renormalization cycle of $(F, \mathcal{P})$ is c-equivalent to a holomorphic model, which satisfies in addition some prescribed moduli properties.

We always denote by $\mathbb{D}$ the unit disc. A *marked disc* is a pair (Δ, a) with Δ an open hyperbolic disc in $\overline{\mathbb{C}}$ and a marked point $a \in \Delta$. An *equipotential* γ of (Δ, a) is a Jordan curve that is mapped to a round circle under a conformal representation $\chi : \Delta \rightarrow \mathbb{D}$ with $\chi(a) = 0$. The *potential* of such a γ is defined to be $\kappa(\gamma) := \text{mod}A(\partial\Delta, \gamma)$, the modulus of the annulus between $\partial\Delta$ and γ . These notions do not depend on the choice of χ . The map κ maps the set of equipotentials bijectively onto the open interval $]0, +\infty[$. For example in the marked disc $(\mathbb{D}, 0)$, the circle $\{|z| = e^{-v}\}$ is an equipotential with potential v (we define $\text{mod}\{r < |z| < 1\} := -\log r$).

Let f be a postcritically finite rational map with non-empty Fatou set. The Julia set $\mathcal{J}_f$ is connected and each Fatou component Δ is canonically a marked disc marked by the unique eventually periodic point a in Δ . We call (Δ, a) a *marked Fatou component* of f . The equipotentials of these marked Fatou components will be called *equipotentials* of f . Notice that equipotentials in a periodic Fatou component correspond to round circles in Böttcher coordinates. We will use κ to denote the potential function of these marked discs.

Marked set $\mathcal{P}_S$. Again consider each $\mathcal{L}$ -piece S as being contained in a distinct copy $\overline{\mathbb{C}}_S$ of the Riemann sphere. Mark one point in each component of $\overline{\mathbb{C}}_S \setminus S$. Set $\mathcal{P}_S$ to be the union of $\mathcal{P} \cap S$ with these marked points. By definition a piece S is an $\mathcal{C}$ -piece if and only if $\#\mathcal{P}_S \geq 3$.

As $(F, \mathcal{P})$ is of constant complexity, there is an induced map F_* on the set of $\mathcal{C}$ -pieces. Let $S_1, \dots, S_p$ be a periodic cycle of $\mathcal{C}$ -pieces for F_* , i.e. for $i = 1, \dots, p$ we have $F(E_i) = S_{i+1}$ (set $S_{p+1} = S_1$), where E_i is the unique complex $\mathcal{E}$ -piece in S_i . Denote by $\overline{\mathbb{C}}_i = \overline{\mathbb{C}}_{S_i}$ for simplicity.

We will prove:

Theorem 7.1. *Denote by D_* the $(F, \mathcal{P})$ -transition matrix of the set of the boundary curves of $S_1 \cup \dots \cup S_p$. Let $u > 0$ be any positive vector such that $D_* u < u$. Then there are pairs of quasi-conformal maps $(\phi_{S_i}, \psi_{S_i}) : \overline{\mathbb{C}}_{S_i} \rightarrow \overline{\mathbb{C}}_{S'_i}$ and holomorphic maps $R_i : \overline{\mathbb{C}}_{S'_i} \rightarrow \overline{\mathbb{C}}_{S'_{i+1}}$ for $1 \leq i \leq p$ such that:*

- (a) $\phi_{S_i} = \psi_{S_i}$ on $\partial S_i \cup (\mathcal{P} \cap S_i)$, and ϕ_{S_i} is isotopic to ψ_{S_i} rel $\partial S_i \cup (\mathcal{P} \cap S_i)$;
- (b) $\phi_{S_{i+1}} \circ F \circ \psi_{S_i}^{-1}|_{\psi_{S_i}(E_i)} = R_i|_{\psi_{S_i}(E_i)}$;
- (c) the return map $f_{S_i} := R_{i-1} \circ \dots \circ R_1 \circ R_p \circ \dots \circ R_i$ is a postcritically finite rational map whose conformal conjugacy class depends only on F and S_i ;
- (d) for each $i \in \{1, \dots, p\}$, for each Jordan curve $\gamma \subset \partial S_i$, and for β_γ the curve in ∂E_i homotopic to γ within $S_i \setminus \mathcal{P}$, both $\phi_{S_i}(\gamma)$ and $\psi_{S_i}(\beta_\gamma)$ are equipotentials in the same

marked Fatou component of f_{S_i} with potentials

$$\kappa(\phi_{S_i}(\gamma)) = u(\gamma) \quad \text{and} \quad \kappa(\psi_{S_i}(\beta_\gamma)) = \frac{u(F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})}. \quad (10)$$

Note that (a) and (b) together assert that $R : \bigcup \psi_{S_i}(E_i) \rightarrow \bigcup \phi_{S_i}(S_i)$, marked by $\bigcup \phi_{S_i}(\mathcal{P} \cap S_i)$, with $R = R_i$ on $\psi_{S_i}(E_i)$, is a holomorphic repelling system c-equivalent to $(\bigcup E_i \xrightarrow{F} \bigcup S_i, \mathcal{P} \cap \bigcup S_i)$.

7.1 Disc-marked extension and equipotentials

For a repelling system $F : \mathcal{E} \rightarrow \mathcal{L}$ of constant complexity, and any $\mathcal{L}$ -piece S , the above marking $\mathcal{P}_S$ makes each complementary disc of S into a marked disc. We will use κ_S to denote the potential function of these complementary marked discs of S . Let S_1 and S_2 be $\mathcal{C}$ -pieces with $F(E_1) = S_2$ where E_1 is the unique complex $\mathcal{E}$ -piece contained in S_1 . There are many ways to extend $F|_{E_1}$ to a branched covering. We choose the following one to rigidify the extension.

Lemma 7.2. *Let S_1 and S_2 be $\mathcal{C}$ -pieces with $F(E_1) = S_2$ where E_1 is the unique complex $\mathcal{E}$ -piece contained in S_1 . Let ρ be a positive function defined on the set of Jordan curves in ∂S_1 . Then there is a quasi-regular branched covering extension $h : \overline{\mathbb{C}}_{S_1} \rightarrow \overline{\mathbb{C}}_{S_2}$ of $F|_{E_1}$ such that:*

- (a) $h(\overline{\mathbb{C}}_{S_1} \setminus E_1) = \overline{\mathbb{C}}_{S_2} \setminus S_2$.
- (b) $h(\mathcal{P}_{S_1}) \subset \mathcal{P}_{S_2}$ and the critical values of h are contained in $\mathcal{P}_{S_2}$.
- (c) For any Jordan curve $\gamma \subset \partial S_1$, $h(\gamma)$ is an equipotential in a complementary marked disc of S_2 , with potential $\kappa_{S_2}(h(\gamma)) = \rho(\gamma)$.
- (d) h is holomorphic in $\overline{\mathbb{C}}_{S_1} \setminus S_1$.

Such a map h will be called a **disc-marked extension** of $F|_{E_1}$ associated to the function ρ .

Proof. Let α be a boundary component of E_1 , bounding a unique complementary component Δ_α of E_1 . Then $\eta := F(\alpha)$ is a boundary curve of S_2 , and bounds a unique complementary marked disc (Δ_η, b) of S_2 . Set $d := \deg(F : \alpha \rightarrow \eta)$.

Note that Δ_α may contain zero or one complementary component of S . In the former case, define $h_\alpha : \Delta_\alpha \rightarrow \Delta_\eta$ to be a quasi-conformal map if $d = 1$, or a quasi-regular map with a unique critical value b if $d > 1$, such that $h_\alpha|_\alpha = F|_\alpha$.

In the latter case α is homotopic within $S_1 \setminus \mathcal{P}$ to a unique boundary curve γ of S_1 . Let Δ_γ be the component of $\overline{\mathbb{C}}_{S_1} \setminus S_1$ enclosed by γ . Then $\Delta_\gamma \subset \Delta_\alpha$, and Δ_γ together with the marked point $a \in \Delta_\gamma$ is a complementary marked disc of S_1 .

Let η_1 be the equipotential in the marked disc (Δ_η, b) with potential $\kappa_{S_2}(\eta_1) = \rho(\gamma)$. Denote by Δ_1 the disc enclosed by η_1 and contained in Δ_η . Define $h_\gamma : \Delta_\gamma \rightarrow \Delta_1$ by $h_\gamma(z) = \varphi_1^{-1} \circ (\varphi(z))^d$, where φ (resp. φ_1) is a conformal map from the marked disc (Δ_γ, a) (resp. (Δ_1, b)) onto the unit disc $\mathbb{D}$ with $\varphi(a) = 0$ (resp. $\varphi_1(b) = 0$). Then there is a quasi-regular covering $h_{\alpha\gamma}$ from $\Delta_\alpha \setminus \overline{\Delta}_\gamma$ onto $\Delta_\eta \setminus \overline{\Delta}_1$ so that $h_{\alpha\gamma}|_\alpha = F|_\alpha$ and $h_{\alpha\gamma}|_\gamma = h_\gamma|_\gamma$. Set $h_\alpha := h_\gamma$ on Δ_γ and $h_\alpha := h_{\alpha\gamma}$ on $\Delta_\alpha \setminus \overline{\Delta}_\gamma$. Then $h_\alpha : \Delta_\alpha \rightarrow \Delta_\eta$ is also quasi-regular, in particular, holomorphic in Δ_γ .

The map $F|_{E_1}$ together with h_α for all boundary curves of E_1 forms a quasi-regular branched covering $h : \overline{\mathbb{C}}_{S_1} \rightarrow \overline{\mathbb{C}}_{S_2}$. It satisfies the conditions (a)-(d). $\square$

7.2 Spherical holomorphic models

Consider the same marking $\mathcal{P}_S$ (thus the function κ_S) for each $\mathcal{L}$ -piece S as above.

Lemma 7.3. *Let ρ , resp. σ , be two positives functions defined respectively on the set of Jordan curves in $\bigcup_{i=1}^p \partial S_i$, resp. in ∂S_1 . For $1 \leq i \leq p$, let $h_i : \overline{\mathbb{C}}_i \rightarrow \overline{\mathbb{C}}_{i+1}$ be a disc-marked extension of $F : E_i \rightarrow S_{i+1}$ associated to the function ρ , given by Lemma 7.2.*

Then there are pairs of quasi-conformal homeomorphisms (Φ_i, Ψ_i) of $\overline{\mathbb{C}}_i$ onto a distinct copy $\overline{\mathbb{C}}'_i$ of the Riemann sphere, and holomorphic maps $R_i : \overline{\mathbb{C}}'_i \rightarrow \overline{\mathbb{C}}'_{i+1}$ ($i = 1, \dots, p$), such that they satisfy the following conditions:

- (1) Ψ_i is isotopic to Φ_i rel $\mathcal{P}_{S_i}$, and Φ_i is holomorphic on $\overline{\mathbb{C}}_i \setminus S_i$, $i = 1, \dots, p$.
- (2) $R_i \equiv \Phi_{i+1} \circ h_i \circ \Phi_i^{-1}$ for $2 \leq i \leq p$ (with $\Phi_{p+1} = \Phi_1$), and $R_1 \equiv \Phi_2 \circ h_1 \circ \Psi_1^{-1}$ (see (13)).
- (3) For any $i = 1, \dots, p$, and $f_i := R_{i-1} \circ \dots \circ R_1 \circ R_p \circ \dots \circ R_i$, we have $f_i = \Phi_i \circ h_{i-1} \circ \dots \circ h_1 \circ h_p \circ \dots \circ h_i \circ \Psi_i^{-1}$ and f_i is a postcritically finite rational map. The conformal conjugacy class of each f_i depends only on F and S_i , but not on the choices of the markings, nor on the functions ρ and σ , nor on h_i, Φ_i, Ψ_i .
- (4) For each Jordan curve $\gamma \subset \partial S_1$, the curve $\Phi_1(\gamma)$ is an equipotential of f_1 with potential $\kappa(\Phi_1(\gamma)) = \sigma(\gamma)$.

Consequently we have:

Corollary 7.4. (1) Fix $2 \leq i \leq p$. The map Φ_i is holomorphic in $\overline{\mathbb{C}}_i \setminus S_i$. For each Jordan curve $\gamma \subset \partial S_i$, and for β_γ the unique curve in ∂E_i homotopic to γ within $S_i \setminus \mathcal{P}$, both $\Phi_i(\gamma)$ and $\Phi_i(\beta_\gamma)$ are equipotentials in the same marked Fatou component of f_i . And their potentials are related as follows:

$$\kappa(\Phi_i(\gamma)) = \frac{\rho(\gamma)}{\deg(F|_{\beta_\gamma})} + \kappa(\Phi_i(\beta_\gamma)), \quad \kappa(\Phi_i(\beta_\gamma)) = \frac{\kappa(\Phi_{i+1} \circ F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})}. \quad (11)$$

(2) For each Jordan curve $\gamma \subset \partial S_1$, and for β_γ the curve in ∂E_1 homotopic to γ within $S_1 \setminus \mathcal{P}$, the curve $\Psi_1(\beta_\gamma)$ is an equipotential in the marked Fatou component of f_1 that contains $\Phi_1(\gamma)$, with potential

$$\kappa(\Psi_1(\beta_\gamma)) = \frac{\kappa(\Phi_2 \circ F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})}. \quad (12)$$

See the following commutative diagram.

$$\begin{array}{ccccccc}

 \overline{\mathbb{C}}'_1 & \xrightarrow{R_1} & \overline{\mathbb{C}}'_2 & \xrightarrow{R_2} & \overline{\mathbb{C}}'_3 & \longrightarrow \dots \longrightarrow & \overline{\mathbb{C}}'_p & \xrightarrow{R_p} & \overline{\mathbb{C}}'_1
 \end{array}$$

Proof of Lemma 7.3.

Denote by $H : E \rightarrow S_1$ the renormalization of F relative to S_1 . Set

$$h := h_p \circ \cdots \circ h_2 \circ h_1 : \overline{\mathcal{C}}_1 \rightarrow \overline{\mathcal{C}}_1.$$

Then $h(\mathcal{P}_{S_1}) \subset \mathcal{P}_{S_1}$ and $\mathcal{P}_h \subset \mathcal{P}_{S_1}$. Clearly, $(h, \mathcal{P}_{S_1})$ is a marked extension of the renormalization $H : E \rightarrow S_1$.

It is easy to see that the c-equivalence class of $(h, \mathcal{P}_{S_1})$ does not depend on the choice of extensions.

Now the assumption that $(F, \mathcal{P})$ has no renormalized obstructions implies that $(H, \mathcal{P} \cap S_1)$ as a repelling system, has no Thurston obstructions. This in turn implies that $(h, \mathcal{P}_{S_1})$ has an orbifold distinct from $(2, 2, 2, 2)$ and has no Thurston obstructions, as follows: Since the marked points in $\overline{\mathcal{C}}_1 \setminus S_1$ map to themselves by h , they are eventually h -periodic. Let b be a periodic marked point in $\overline{\mathcal{C}}_1 \setminus S_1$ with period $k \geq 1$. Denote by Δ_b the component of $\overline{\mathcal{C}}_1 \setminus S_1$ that contains the marked point b and $\gamma_b := \partial \Delta_b$. Then there is unique component of $h^{-k}(\gamma)$, denoted by β , such that β is homotopic to γ rel $\mathcal{P}_{S_1}$. Note that γ is contained in the boundary multicurve Y and β is a component of $F^{-kp}(\gamma)$ in S_1 . Thus the assumption $\lambda(W_Y) < 1$ implies that

$$\deg(F^{kp} : \beta \rightarrow \gamma) = \deg(h^k : \beta \rightarrow \gamma) = \deg_b h^k > 1.$$

This implies that h has a periodic critical point (in the cycle of b). Therefore $(h, \mathcal{P}_{S_1})$ has an orbifold distinct from $(2, 2, 2, 2)$. Now any multicurve within $\overline{\mathcal{C}} \setminus \mathcal{P}_{S_1}$ can be represented by a multicurve within $S_1 \setminus \mathcal{P}_{S_1} = S_1 \setminus (\mathcal{P} \cap S_1)$. So its $(h, \mathcal{P}_{S_1})$ -transition matrix is equal to its $(H, \mathcal{P} \cap S_1)$ -transition matrix, thus has the same leading eigenvalue, which is less than one. This implies $(h, \mathcal{P}_{S_1})$ has no Thurston obstructions.

Applying Thurston Theorem to get (ϕ, ψ) and f_1 . We can then apply Thurston Theorem 3.2 to obtain a pair of quasi-conformal maps (ϕ, ψ) from $\overline{\mathcal{C}}_1$ onto $\overline{\mathcal{C}}'_1$ and a rational map f_1 , whose conformal conjugacy class depends only on the c-equivalence class of $(h, \mathcal{P}_{S_1})$ (which depends only on $(H, \mathcal{P} \cap S_1)$), such that ψ is isotopic to ϕ rel $\mathcal{P}_{S_1}$ and $f_1 = \phi \circ h \circ \psi^{-1}$. In particular f_1 does not depend on the choice of the functions ρ and σ . Moreover, $\mathcal{P}_{f_1} \subset \phi(\mathcal{P}_{S_1})$.

As any periodic cycle (b) of marked points in $\overline{\mathcal{C}} \setminus S_1$ contains a critical point of h , the cycle $(\phi(b))$ is a superattracting periodic cycle for f_1 . Consequently, for every marked point a in $\overline{\mathcal{C}}_1 \setminus S_1$, $\phi(a)$ is an eventually superattracting periodic point of f_1 .

From (ϕ, ψ) to (Φ_1, Ψ_1) . For every marked point a in $\overline{\mathcal{C}}_1 \setminus S_1$, denote by Δ_a the component of $\overline{\mathcal{C}}_1 \setminus S_1$ that contains the point a and $\gamma_a = \partial \Delta_a$. Denote by η_a the equipotential of the Fatou component of f_1 containing $\phi(a)$ (with $\phi(a)$ as a marked point), with potential $\kappa(\eta_a) = \sigma(\gamma_a)$. Then there is a quasi-conformal map Φ_1 in the isotopy (rel $\mathcal{P}_{S_1}$) class of ϕ such that for every marked point a in $\overline{\mathcal{C}}_1 \setminus S_1$, we have $\Phi_1(\gamma_a) = \eta_a$ (this is because γ_a , resp. η_a , is peripheral around the point $a \in \mathcal{P}_{S_1}$, resp. the point $\phi(a) \in \phi(\mathcal{P}_{S_1})$). Moreover, Φ_1 can be taken to be holomorphic on $\bigcup_a \Delta_a = \overline{\mathcal{C}}_1 \setminus S_1$.

As Φ_1 is isotopic to ϕ rel $\mathcal{P}_{S_1}$, there is a quasi-conformal map $\Psi_1 : \overline{\mathcal{C}}_1 \rightarrow \overline{\mathcal{C}}'_1$ such that it is isotopic to ψ rel $\mathcal{P}_{S_1}$ and $\Phi_1 \circ h \circ \Psi_1^{-1} = f_1$.

Getting (in order) $\Phi_p, R_p, \Phi_{p-1}, R_{p-1}, \dots, \Phi_2, R_2$ and then R_1 . This is illustrated in the following diagrams:

$$\begin{array}{ccccccc} \overline{\mathcal{C}}_2 & \xrightarrow{h_2} & \overline{\mathcal{C}}_3 & \longrightarrow & \cdots & \longrightarrow & \overline{\mathcal{C}}_p & \xrightarrow{h_p} & \overline{\mathcal{C}}_1 & & \overline{\mathcal{C}}_1 & \xrightarrow{h_1} & \overline{\mathcal{C}}_2 \\ \downarrow \Phi_2 & & \downarrow \Phi_3 & & & & \downarrow \Phi_p & & \downarrow \Phi_1 & \text{and} & \Psi_1 \downarrow & & \downarrow \Phi_2 \\ \overline{\mathcal{C}}'_2 & \xrightarrow{R_2} & \overline{\mathcal{C}}'_3 & \longrightarrow & \cdots & \longrightarrow & \overline{\mathcal{C}}'_p & \xrightarrow{R_p} & \overline{\mathcal{C}}'_1 & & \overline{\mathcal{C}}'_1 & \xrightarrow{R_1} & \overline{\mathcal{C}}'_2 \end{array} \quad (13)$$

More precisely pull-back the complex structure of $\overline{\mathbb{C}}'_1$ to $\overline{\mathbb{C}}_p$ by $\Phi_1 \circ h_p$, we have a quasi-conformal map $\Phi_p : \overline{\mathbb{C}}_p \rightarrow \overline{\mathbb{C}}'_p$ such that $R_p := \Phi_1 \circ h_p \circ \Phi_p^{-1}$ is holomorphic.

As a disc-marked extension, we know that h_p is holomorphic in $\overline{\mathbb{C}}_p \setminus S_p$ whose h_p -image is contained in $\overline{\mathbb{C}}_1 \setminus S_1$. Combining with the result that Φ_1 is holomorphic in $\overline{\mathbb{C}}_1 \setminus S_1$ and the equation $R_p \circ \Phi_p = \Phi_1 \circ h_p$, we see that Φ_p is holomorphic in $\overline{\mathbb{C}}_p \setminus S_p$.

Inductively, for $i = p-1, \dots, 2$, we have a quasi-conformal map $\Phi_i : \overline{\mathbb{C}}_i \rightarrow \overline{\mathbb{C}}'_i$ such that $R_i := \Phi_{i+1} \circ h_i \circ \Phi_i^{-1}$ is holomorphic and Φ_i is holomorphic in $\overline{\mathbb{C}}_i \setminus S_i$.

Set finally $R_1 := \Phi_2 \circ h_1 \circ \Psi_1^{-1}$. Then $R_p \circ \dots \circ R_2 \circ R_1 = f_1$. Therefore R_1 is also holomorphic and Ψ_1 is holomorphic in $\overline{\mathbb{C}}_1 \setminus S_1$.

Getting Ψ_i and f_i . As a disc-marked extension, we know that the critical values of h_i is contained in $\mathcal{P}_{S_{i+1}}$ and $h_i(\mathcal{P}_{S_i}) \subset \mathcal{P}_{S_{i+1}}$ for $1 \leq i \leq p$. Because Ψ_1 is isotopic to Φ_1 rel $\mathcal{P}_{S_1}$, there is a quasi-conformal map $\Psi_p : \overline{\mathbb{C}}_p \rightarrow \overline{\mathbb{C}}'_p$ such that Ψ_p is isotopic to Φ_p rel $\mathcal{P}_{S_p}$ and $\Psi_1 \circ h_p = R_p \circ \Psi_p$. Inductively, there is a quasi-conformal map $\Psi_i : \overline{\mathbb{C}}_i \rightarrow \overline{\mathbb{C}}'_i$ for $i = p-1, \dots, 2$, such that Ψ_i is isotopic to Φ_i rel $\mathcal{P}_{S_i}$ and $\Psi_{i+1} \circ h_i = R_i \circ \Psi_i$. Set then $f_i := R_{i-1} \circ \dots \circ R_1 \circ R_p \circ \dots \circ R_i$. Now we have the following commutative diagrams:

$$\begin{array}{ccccccc} \overline{\mathbb{C}}_i & \xrightarrow{h_i} & \dots & \xrightarrow{h_p} & \overline{\mathbb{C}}_1 & \xrightarrow{h_1} & \overline{\mathbb{C}}_2 & \longrightarrow & \dots & \xrightarrow{h_{i-1}} & \overline{\mathbb{C}}_i & & \overline{\mathbb{C}}_i & \xrightarrow{*} & \overline{\mathbb{C}}_i \\ \Psi_i \downarrow & & \Psi_p \downarrow & & \Psi_1 \downarrow & & \downarrow \Phi_2 & & & & \downarrow \Phi_i & \text{and} & \Psi_i \downarrow & & \downarrow \Phi_i \\ \overline{\mathbb{C}}'_i & \xrightarrow{R_i} & \dots & \xrightarrow{R_p} & \overline{\mathbb{C}}'_1 & \xrightarrow{R_1} & \overline{\mathbb{C}}'_2 & \longrightarrow & \dots & \xrightarrow{R_{i-1}} & \overline{\mathbb{C}}'_i & & \overline{\mathbb{C}}'_i & \xrightarrow{f_i} & \overline{\mathbb{C}}'_i \end{array}$$

It is easy to see that $f_i = \Phi_i \circ h_{i-1} \circ \dots \circ h_1 \circ h_p \circ \dots \circ h_i \circ \Psi_i^{-1}$ for $i \geq 2$. The above formula shows that f_i is c-equivalent to $h_{i-1} \circ \dots \circ h_1 \circ h_p \circ \dots \circ h_i$, which is postcritically finite. So f_i is also postcritically finite and $\mathcal{P}_{f_i} \subset \Phi_i(\mathcal{P}_{S_i})$. Clearly it is c-equivalent to a marked extension of the renormalization relative to S_i . Again its conformal conjugacy class depends only on F and S_i . $\square$

Proof of Corollary 7.4. Notice that $f_{i+1} \circ R_i = R_i \circ f_i$, i.e., R_i is a holomorphic (semi-)conjugacy from f_i to f_{i+1} (set $f_{p+1} = f_1$). It is classical that their Julia sets are related by $\mathcal{J}(f_i) = R_i^{-1}(\mathcal{J}(f_{i+1}))$. Note that the critical values of R_i are contained in $\Phi_{i+1}(\mathcal{P}_{S_{i+1}})$, which is eventually periodic under f_{i+1} . We see that R_i maps equipotentials of f_i to equipotentials of f_{i+1} .

As a disc-marked extension, for each Jordan curve $\gamma \subset \partial S_p$, the curve $h_p(\gamma)$ lies on an equipotential in a complementary marked disc of S_1 . Because each Jordan curve in $\partial \Phi_1(S_1)$ lies on an equipotential of f_1 and Φ_1 is holomorphic in $\overline{\mathbb{C}}_1 \setminus S_1$, the curve $h_p(\gamma)$ goes to an equipotential of f_1 by Φ_1 . This equipotential of f_1 is pulled back by R_p to equipotentials of f_p . Thus $\Phi_p(\gamma)$ lies on an equipotential of f_p . Inductively, we have that each Jordan curve in $\partial \Phi_i(S_i)$ lies on an equipotential of f_i for $i = 1, \dots, p$.

Similarly, each curve in $\Phi_i(\partial E_i)$ lies on an equipotential of f_i for $i \geq 2$ and each curve in $\Psi_1(\partial E_1)$ lies on an equipotential of f_1 .

Fix $i \in \{1, \dots, p\}$. For each Jordan curve $\gamma \subset \partial S_i$, and for β_γ the curve in ∂E_i homotopic to γ within $S_i \setminus \mathcal{P}$, we have that $h_i(\beta_\gamma) = F(\beta_\gamma)$ is a curve in ∂S_{i+1} . Note that $\Phi_{i+1} \circ h_i(\beta_\gamma) = R_i \circ \Phi_i(\beta_\gamma)$ if $i \neq 1$ (with $\Phi_{p+1} = \Phi_1$) or $\Phi_2 \circ h_1(\beta_\gamma) = R_1 \circ \Psi_1(\beta_\gamma)$ if $i = 1$. Their potentials are related by:

$$\kappa(\Phi_i(\beta_\gamma)) = \frac{\kappa(\Phi_{i+1} \circ F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \text{ if } i \neq 1 \quad \text{or} \quad \kappa(\Psi_1(\beta_\gamma)) = \frac{\kappa(\Phi_2 \circ F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \text{ if } i = 1.$$

Fix now $2 \leq i \leq p$. By the construction of h_i in Lemma 7.2, the curve $h_i(\gamma)$ is

an equipotential with potential $\rho(\gamma)$ in a complementary marked disc of S_{i+1} . We have $\text{mod} h_i(A(\gamma, \beta_\gamma)) = \rho(\gamma)$, where $A(\gamma, \beta_\gamma)$ is the annulus between them. Notice that Φ_{i+1} is conformal in $\overline{\mathbb{C}}_{i+1} \setminus S_{i+1}$. We also have $\text{mod} \Phi_{i+1} \circ h_i(A(\gamma, \beta_\gamma)) = \rho(\gamma)$. From the equation $R_i \circ \Phi_i = \Phi_{i+1} \circ h_i$, we get

$$\kappa(\Phi_i(\gamma)) - \kappa(\Phi_i(\beta_\gamma)) = \text{mod} \Phi_i(A(\gamma, \beta_\gamma)) = \frac{\rho(\gamma)}{\deg(F|_{\beta_\gamma})}.$$

□

Remark 1. For every i , if we make a normalization by requiring that three given distinct points in $\mathcal{P}_{S_i}$ (note that $\#\mathcal{P}_{S_i} \geq 3$ since S_i is a $\mathcal{C}$ -piece) go to $(0, -1, \infty)$ under the action of Φ_i , then f_i is uniquely determined, as well as the homotopy class (rel $\mathcal{P}_{S_i}$) of Φ_i .

Remark 2. For a F_* -periodic cycle $(S_1, \dots, S_p)$, we have p renormalizations (one for each S_i). Lemma 7.3 shows that none of them has Thurston obstructions if one of them has no Thurston obstructions.

7.3 Proof of Theorem 7.1

Fix now the positive functions σ and ρ as follows:

$$\forall \gamma \subset \partial S_1, \sigma(\gamma) := u(\gamma); \quad \forall \gamma \subset \bigcup_{i=1}^p \partial S_i, \rho(\gamma) := \left(u(\gamma) - \frac{u(F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \right) \deg(F|_{\beta_\gamma}), \quad (14)$$

where β_γ is the curve in $\bigcup_{i=1}^p \partial E_i$ homotopic to γ within $\mathcal{L} \setminus \mathcal{P}$. Note that $\rho(\gamma) > 0$ for every γ by the assumption $D_* u < u$.

Let $(\Phi_i, \Psi_i, R_i, f_i)_{i=1, \dots, p}$ be the collection of maps derived from Lemma 7.3 with the functions ρ and σ defined above. Set $f_{S_i} := f_i$.

Let γ be a Jordan curve in ∂S_1 . Then $\kappa(\Phi_1(\gamma)) = \sigma(\gamma) = u(\gamma)$ by Lemma 7.3 (4).

Let γ be a Jordan curve in ∂S_p and β_γ be the curve in ∂E_p homotopic to γ within $S_p \setminus \mathcal{P}$. We have

$$\kappa(\Phi_p(\gamma)) \stackrel{(11)}{=} \frac{\rho(\gamma)}{\deg(F|_{\beta_\gamma})} + \frac{\kappa(\Phi_1 \circ F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \stackrel{\text{Lem. 7.3.(4)}}{=} \frac{\rho(\gamma)}{\deg(F|_{\beta_\gamma})} + \frac{u(F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \stackrel{(14)}{=} u(\gamma).$$

Inductively, for $i = p-1, \dots, 2$, we have $\kappa(\Phi_i(\gamma)) = u(\gamma)$ for any Jordan curve $\gamma \subset \partial S_i$. Therefore $\kappa(\Phi_i(\gamma)) = u(\gamma)$ for any i and any $\gamma \subset \partial S_i$.

Fix any $i \in \{1, \dots, p\}$. Let β be a curve in ∂E_i non-null-homotopic within $S_i \setminus \mathcal{P}$. By (11) and (12), we have

$$\kappa(\Phi_i(\beta)) = \frac{\kappa(\Phi_{i+1} \circ F(\beta))}{\deg(F|_\beta)} = \frac{u(F(\beta))}{\deg(F|_\beta)} \quad \text{if } i \neq 1 \quad \text{and} \quad \kappa(\Psi_1(\beta)) = \frac{u(F(\beta))}{\deg(F|_\beta)} \quad \text{if } i = 1.$$

Let γ be a Jordan curve in ∂S_1 and β_γ be the Jordan curve in ∂E_1 homotopic to γ within $S_1 \setminus \mathcal{P}$. From the above formula and the fact that $D_* u < u$, we deduce that $\kappa(\Psi_1(\beta_\gamma)) < \kappa(\Phi_1(\gamma))$. This implies that $\Psi_1(E_1) \subset \subset \Phi_1(S_1)$.

For $i = 2, \dots, p$, set $\phi_{S_i} = \psi_{S_i} = \Phi_i$. Set also $\phi_{S_1} = \Phi_1$. Obviously, (a)-(d) hold for $i \geq 2$ by the above computation. Now we want to define ψ_{S_1} .

Notice that $\Psi_1(E_1) \subset \subset \Phi_1(S_1)$ and Ψ_1 is isotopic to Φ_1 rel $\mathcal{P}_{S_1}$. This implies that for each Jordan curve $\gamma \subset \partial S_1$, both γ and $\Psi_1^{-1} \circ \Phi_1(\gamma)$ are contained in the same disk component

Δ of $\overline{\mathbb{C}}_1 \setminus E_1$, and are homotopic within $\Delta \setminus \{a\}$, where a is the unique point of $\mathcal{P}_{S_1}$ in Δ . Therefore there is a quasi-conformal map η of $\overline{\mathbb{C}}_1$ isotopic to the identity rel $\mathcal{P}_{S_1}$ so that $\eta|_{E_1} = id$ and $\eta = \Psi_1^{-1} \circ \Phi_1$ on $\overline{\mathbb{C}}_1 \setminus S_1$. Set $\hat{\psi} := \Psi_1 \circ \eta$. Then $\hat{\psi}$ is isotopic to Ψ_1 therefore to Φ_1 rel $\mathcal{P}_{S_1}$, with $\hat{\psi}|_{\overline{\mathbb{C}}_1 \setminus S_1} = \Phi_1|_{\overline{\mathbb{C}}_1 \setminus S_1}$ and $\hat{\psi}|_{E_1} = \Psi_1$. This gives already (b).

To get (a), i.e. $\hat{\psi}$ is isotopic to Φ_1 rel $\mathcal{P}_{S_1} \cup \partial S_1$, we need to modify $\hat{\psi}$ on the annuli of $S_1 \setminus E_1$.

Set $\chi = \Phi_1^{-1} \circ \hat{\psi}$. Then by a purely topological argument (see Lemma D.1) there is a homeomorphism T which is the identity outside $S_1 \setminus E_1$ such that $\chi \circ T$ is isotopic to the identity rel $\mathcal{P}_{S_1} \cup (\overline{\mathbb{C}}_1 \setminus S_1)$. Set now $\psi_{S_1} = \hat{\psi} \circ T$. We get both (a) and (b) of the Theorem. Point (d) for $i = 1$ is also derived from the above computation. $\square$

8 Proof of Theorem 5.4

Let now $(\mathcal{E} \xrightarrow{F} \mathcal{L}, \mathcal{P})$ be a marked repelling system of constant complexity, without boundary obstructions nor renormalized obstructions. We prove here that $(F, \mathcal{P})$ is c-equivalent to a holomorphic model. Decompose $\mathcal{L}$ into $\mathcal{O} \sqcup \mathcal{A} \sqcup \mathcal{R} \sqcup \mathcal{C}$ as in (4).

8.1 Choice of the positive vector

Let Y be a boundary multicurve of $(F, \mathcal{P})$. It can be chosen to be the collection of Jordan curves in $\partial \mathcal{C} \cup \partial_+ \mathcal{A}$. By assumption, for the $(F, \mathcal{P})$ -transition matrix W_Y , we have $\lambda(W_Y) < 1$. Applying Lemma A.1, we have a positive vector $v \in \mathbb{R}^Y$ so that $W_Y v < v$, i.e. there is a positive function

$$v : Y \rightarrow \mathbb{R}^+ \quad \text{such that} \quad (W_Y v)_\gamma = \sum_{\eta \in Y} \sum_{\alpha \sim \gamma} \frac{v(\eta)}{\deg(F : \alpha \rightarrow \eta)} < v(\gamma), \quad (15)$$

where the last sum is taken over all curves α in $F^{-1}(\eta)$ that are homotopic to γ within $\mathcal{L} \setminus \mathcal{P}$. Let $C > 0$ be a constant to be determined later. Denote by $\mathbf{1}$ the vector whose every entry is 1. Choose $M > 0$ to be a large number so that $W_Y(Mv) + C\mathbf{1} < Mv$, i.e.

$$\forall \gamma \in Y, \quad \sum_{\eta \in Y} \sum_{\alpha \sim \gamma} \frac{Mv(\eta)}{\deg(F : \alpha \rightarrow \eta)} + C < Mv(\gamma). \quad (16)$$

For any $\gamma \in Y$ the quantity $Mv(\gamma)$ will be the prescribed potential for $\phi_S(\gamma)$, with S the $\mathcal{L}$ -piece admitting γ as a boundary curve.

8.2 Definition of (ϕ_S, ψ_S) and f_S for $\mathcal{C}$ -pieces

Assume at first that $S_1, \dots, S_p$ are $\mathcal{C}$ -pieces with $F(E_i) = S_{i+1}$ and $S_{p+1} = S_1$, where E_i is the unique complex $\mathcal{E}$ -piece in S_i . Set $u := Mv|_{\bigcup_i \partial S_i}$. We have $D_* u < u$ for D_* the $(F, \mathcal{P})$ -transition matrix of the set of the boundary curves of $S_1 \cup \dots \cup S_p$. We construct $\phi_{S_i}, \psi_{S_i}, R_{S_i}$ and f_{S_i} according to Theorem 7.1 for $i = 1, \dots, p$. We do so for every periodic cycle of F_* .

Assume now that S is a non- F_* -periodic $\mathcal{C}$ -piece. Then there are $\mathcal{C}$ -pieces $S =: S_{-k}, S_{-k+1}, \dots, S_0$ ($k > 0$) such that S_i is not F_* -periodic for $i < 0$ but S_0 is F_* -periodic, and $F(E_i) = S_{i+1}$ for $i < 0$, where E_i is the unique complex $\mathcal{E}$ -piece in S_i .

Denote by $\overline{\mathbb{C}}_i = \overline{\mathbb{C}}_{S_i}$ for simplicity. As S_0 is F_* -periodic, we have already constructed a quasi-conformal map $\phi_{S_0} : \overline{\mathbb{C}}_0 \rightarrow \overline{\mathbb{C}}'_0$ and a postcritically finite rational map f_0 on $\overline{\mathbb{C}}'_0$ such that they satisfy the conditions of Theorem 7.1 for $u = Mv$.

For $i = -1, -2, \dots, -k$, let $h_i : \overline{\mathbb{C}}_i \rightarrow \overline{\mathbb{C}}_{i+1}$ be a disc-marked extension of $F : E_i \rightarrow S_{i+1}$, given by Lemma 7.2, associated to the function

$$\rho(\gamma) := \left(Mv(\gamma) - \frac{Mv(F(\beta_\gamma))}{\deg(F|_{\beta_\gamma})} \right) \deg(F|_{\beta_\gamma}),$$

where γ is a Jordan curve in ∂S_i and β_γ is the curve in ∂E_i homotopic to γ within $S_i \setminus \mathcal{P}$. As before, there are quasi-conformal maps $\phi_{S_i} = \phi_i : \overline{\mathbb{C}}_i \rightarrow \overline{\mathbb{C}}'_i$ and holomorphic maps $R_i : \overline{\mathbb{C}}'_i \rightarrow \overline{\mathbb{C}}'_{i+1}$ such that the following diagram commutes:

$$\begin{array}{ccccccc} \overline{\mathbb{C}}_{-k} & \xrightarrow{h_{-k}} & \overline{\mathbb{C}}_{-k+1} & \xrightarrow{h_{-k+1}} & \dots & \xrightarrow{h_{-1}} & \overline{\mathbb{C}}_0 \\ \downarrow \phi_{-k} & & \downarrow \phi_{-k+1} & & & & \downarrow \phi_0 = \phi_{S_0} \\ \overline{\mathbb{C}}'_{-k} & \xrightarrow{R_{-k}} & \overline{\mathbb{C}}'_{-k+1} & \xrightarrow{R_{-k+1}} & \dots & \xrightarrow{R_{-1}} & \overline{\mathbb{C}}'_0 \end{array}$$

Because $h_i(\mathcal{P}_{S_i}) \subset \mathcal{P}_{S_{i+1}}$ and every critical value (if exists) of h_i lies on $\mathcal{P}_{S_{i+1}}$, we have $R_i(\phi_i(\mathcal{P}_{S_i})) \subset \phi_{i+1}(\mathcal{P}_{S_{i+1}})$, and every critical value of $R_{-1} \circ \dots \circ R_i$ lies on $\phi_0(\mathcal{P}_{S_0})$.

Set $f_{S_i} := R_{-1} \circ \dots \circ R_i$. Let $b \in \overline{\mathbb{C}}_i \setminus S_i$ be a marked point. Then $f_{S_i} \circ \phi_i(b)$ is the center of a marked Fatou component Δ of f_0 . The component $\Delta_{\phi_i(b)}$ of $f_{S_i}^{-1}(\Delta)$ that contains $\phi_i(b)$ is a disc. We will call $(\Delta_{\phi_i(b)}, \phi_i(b))$ a *canonical marked disc*.

The name 'canonical' means that up to a Möbius transformation, the configuration formed by these marked discs is uniquely determined. Note that when a disc-marked extension h_i is chosen, up to a Möbius transformation, ϕ_i is uniquely determined by ϕ_{i-1} . As ϕ_{i-1} varies in its homotopy class, ϕ_i varies simultaneously in its homotopy class while R_i remains unchanged. On the other hand various choices of disc-marked extensions are related by quasi-conformal maps. More precisely, if $\tilde{h}_i$ is another choice of the disc-marked extension, then there is a quasi-conformal map ξ of $\overline{\mathbb{C}}_i$ isotopic to the identity rel $\mathcal{P}_{S_i}$, such that $\tilde{h}_i = h_i \circ \xi$. Now set $\tilde{\phi}_i = \phi_i \circ \xi$, we get the same holomorphic map R_i . This implies that the maps f_i are independent of the extensions (but may depend on the marking). In particular, the canonical marked discs are independent of the large number M involved in the function ρ (therefore involved in the extensions h_i).

Lemma 8.1. *With the assumption above, for any $i = -k, \dots, -1$, there are quasi-conformal maps $\psi_{S_i} = \phi_{S_i} : \overline{\mathbb{C}}_{S_i} \rightarrow \overline{\mathbb{C}}'_{S_i}$ such that:*

- (1) $R_i := \phi_{S_{i+1}} \circ h_i \circ \phi_{S_i}^{-1}$ is holomorphic and is independent of M .
- (2) For any marked point $b \in \mathcal{P}_{S_i} \setminus S_i$, denote by γ_b the component of ∂S_i that separates b from $S_i \setminus \gamma_b$ and by α_b the component of ∂E_i that separates b from $E_i \setminus \alpha_b$. Then both $\phi_{S_i}(\gamma_b)$ and $\phi_{S_i}(\alpha_b)$ are equipotentials in the canonical marked disc $(\Delta_{\phi_{S_i}(b)}, \phi_{S_i}(b))$ with potentials

$$\kappa(\phi_{S_i}(\gamma_b)) = Mv(\gamma_b) \quad \text{and} \quad \kappa(\phi_{S_i}(\alpha_b)) = \kappa(\psi_{S_i}(\alpha_b)) = \frac{Mv(F(\alpha_b))}{\deg(F|_{\alpha_b})}. \quad (17)$$

Proof. (1) is obvious. The proof of (2) is quite easy by following the same argument as before. $\square$

8.3 Definition of (ϕ_S, ψ_S) for other $\mathcal{L}$ -pieces

Define $\phi_S = \psi_S = id$ for all $\mathcal{O} \cup \mathcal{R}$ -pieces. Assume that S is an $\mathcal{A}$ -piece. Then it is a closed annulus and one of its boundary curve, say γ , is contained in the boundary multicurve Y . We define ϕ_S to be a quasi-conformal map from S to a round annulus S' in $\overline{\mathcal{C}}_{S'}$ with modulus

$$\text{mod } \phi_S(S) = Mv(\gamma). \quad (18)$$

We will define a map ψ_A for all annular components A of $\mathcal{L} \setminus \mathcal{E}^m$, including the $\mathcal{A}$ -pieces. For this we decompose $\mathcal{E}$ into $\mathcal{E}^m \sqcup \mathcal{E}^2 \sqcup \mathcal{E}^0$ as follows:

- $\mathcal{E}^m$ is the union of complex $\mathcal{E}$ -pieces;
- $\mathcal{E}^0$ is the union of $\mathcal{E}$ -pieces which are contained in a disk $D \subset \mathcal{L}$ with $\#(D \cap \mathcal{P}) \leq 1$;
- $\mathcal{E}^2$ is the union of $\mathcal{E} \setminus \mathcal{E}^0$ -pieces which are contained in an annulus $A \subset \mathcal{L}$ with $A \cap \mathcal{P} = \emptyset$.

Clearly, the above three sets are mutually disjoint. Topologically, $\mathcal{E}^m \subset \mathcal{C}$ and $\mathcal{E}^2 \subset \mathcal{C} \cup \mathcal{A}$. Dynamically, $F^{-1}(\mathcal{O} \cup \mathcal{R}) \subset \mathcal{E}^0$ and $F^{-1}(\mathcal{A}) \subset \mathcal{E}^2 \cup \mathcal{E}^0$.

See Figures 2.

Figure 2: The $\mathcal{L}$ -pieces are bounded by thick curves. Light grey ones are $\mathcal{E}^m$ -pieces, darker-greys, for example E and T , are $\mathcal{E}^2$ -pieces. Hatched ones are $\mathcal{E}^0$ -pieces (they may appear in any, necessarily disc or annular, component of $\mathcal{L} \setminus (\mathcal{E}^m \cup \mathcal{E}^2)$, and may be nested in each others holes).

1. Definition of an auxiliary map φ_E for $\mathcal{E}^2$ -pieces.

Assume that E is a $\mathcal{E}^2$ -piece and S is an $\mathcal{L}$ -piece with $E \subset S$. Set $\widehat{S} := F(E)$. Then both S and $\widehat{S}$ are contained in $\mathcal{C} \cup \mathcal{A}$. Decompose $\mathcal{E}^2$ into $\mathcal{E}^{(2,2)} \sqcup \mathcal{E}^{(2,m)}$ so that $F(\mathcal{E}^{(2,2)}) \subset \mathcal{A}$ and $F(\mathcal{E}^{(2,m)}) \subset \mathcal{C}$.

If $\widehat{S}$ is an $\mathcal{A}$ -piece, then there is a quasi-conformal map φ_E from E onto a closed round annulus such that $\phi_{\widehat{S}} \circ F \circ \varphi_E^{-1}$ is holomorphic in the interior of $\varphi_E(E)$.

Let γ be one of the two boundary curves in $\partial\widehat{S}$ with $\gamma \in Y$. Then there is a Jordan curve β in ∂E so that $F(\beta) = \gamma$. From (18), we have:

$$\text{mod } \varphi_E(E) = \frac{\text{mod } \phi_{\widehat{S}}(\widehat{S})}{\deg F|_E} = \frac{Mv(F(\beta))}{\deg(F|_\beta)}. \quad (19)$$

Now assume $\widehat{S}$ is a $\mathcal{C}$ -piece. Then there is a quasi-regular branched covering $h_E : \overline{\mathbb{C}}_S \rightarrow \overline{\mathbb{C}}_{\widehat{S}}$ such that $h_E|_E = F|_E$, $h_E(E^c) = \widehat{S}^c$ and every critical value of h_E is contained in $\mathcal{P}_{\widehat{S}}$. As before, we have a quasi-conformal map φ_E of $\overline{\mathbb{C}}$ such that $R_E := \phi_{\widehat{S}} \circ h_E \circ \varphi_E^{-1}$ is holomorphic from $\overline{\mathbb{C}}_{S'}$ to $\overline{\mathbb{C}}_{\widehat{S}'}$.

$$\begin{array}{ccccccc} \overline{\mathbb{C}}_S & \supset & S & \supset & E & \xrightarrow{\varphi_E} & \varphi_E(E) \subset \overline{\mathbb{C}}_{S'} \\ h_E \downarrow & & & & F \downarrow & & \downarrow R_E \\ \overline{\mathbb{C}}_{\widehat{S}} & \supset & \widehat{S} & \xrightarrow{\phi_{\widehat{S}}} & \widehat{S}' & \subset & \overline{\mathbb{C}}_{\widehat{S}'} \end{array}, \quad \begin{array}{ccc} \alpha, \beta & \xrightarrow{\varphi_E} & \Delta_{a'}, \Delta_{b'} \\ F \downarrow & & \downarrow R_E \\ & \xrightarrow{\phi_{\widehat{S}}} & \Delta_a, \Delta_b \end{array}$$

Note that ∂E has exactly two boundary curves α and β that are non-null-homotopic within $S \setminus \mathcal{P}$. They are homotopic to each other within $S \setminus \mathcal{P}$. From Theorem 7.1 and Lemma 8.1, we know that $\phi_{\widehat{S}} \circ F(\alpha)$ (resp. $\phi_{\widehat{S}} \circ F(\beta)$) is an equipotential, in a marked disc (Δ_a, a) (resp. (Δ_b, b)) of the postcritically finite rational map $f_{\widehat{S}}$ when $\widehat{S}$ is F_* -periodic, or in a canonical marked disc, denoted also by (Δ_a, a) (resp. (Δ_b, b)) otherwise, whose potentials are

$$\kappa(\phi_{\widehat{S}} \circ F(\alpha)) = Mv(F(\alpha)), \quad \kappa(\phi_{\widehat{S}} \circ F(\beta)) = Mv(F(\beta)).$$

Let $\Delta_{a'}$ (resp. $\Delta_{b'}$) be the component of $R_E^{-1}(\Delta_a)$ (resp. $R_E^{-1}(\Delta_b)$) that contains $\varphi_E(\alpha)$ (resp. $\varphi_E(\beta)$). Then $\Delta_{a'}$ and $\Delta_{b'}$ are disjoint discs since neither $\Delta_a \setminus \{a\}$ and $\Delta_b \setminus \{b\}$ contains critical values of R_E . Set $a' := \Delta_{a'} \cap R_E^{-1}(a)$ and $b' := \Delta_{b'} \cap R_E^{-1}(b)$. Then $(\Delta_{a'}, a')$ and $(\Delta_{b'}, b')$ are disjoint marked discs in $\overline{\mathbb{C}}_{S'}$. Moreover they are independent of the choice of M , because (Δ_a, a) and (Δ_b, b) are independent of the choice of M .

Clearly, $\varphi_E(\alpha)$ and $\varphi_E(\beta)$ are equipotentials with potentials

$$\kappa(\varphi_E(\alpha)) = \frac{Mv(F(\alpha))}{\deg F|_\alpha} \quad \text{and} \quad \kappa(\varphi_E(\beta)) = \frac{Mv(F(\beta))}{\deg F|_\beta}.$$

Let $A(E) = A(\alpha, \beta)$ denote the annulus bounded by α and β . Applying Lemma B.1, there is a constant $C(E) > 0$ which is independent of the choice of M , such that

$$\frac{Mv(F(\alpha))}{\deg F|_\alpha} + \frac{Mv(F(\beta))}{\deg F|_\beta} \leq \text{mod } \varphi_E(A(\alpha, \beta)) \leq \frac{Mv(F(\alpha))}{\deg F|_\alpha} + \frac{Mv(F(\beta))}{\deg F|_\beta} + C(E). \quad (20)$$

The constant C . The set $\mathcal{E}^{(2,m)}$ has only finite many pieces E with $C(E)$ independent of the choice of the number M . Set $C := \sum_E C(E)$. It is also independent of M .

2. Embedding of $\varphi_E(E)$ and construction of ψ_A .

Every $\mathcal{E}^2$ -piece E is contained in $\mathcal{A}$ or in an annular component of $\mathcal{C} \setminus \mathcal{E}^m$. We will embed $\varphi_E(E)$ into the interior of $\mathcal{A} \cup (\mathcal{C} \setminus \mathcal{E}^m)$ so that they are mutually disjoint.

Assume that S is an $\mathcal{A}$ -piece. Let γ be a boundary curve of S with $\gamma \in Y$. From (19) and (20), we have

$$\sum_{E \subset S \cap \mathcal{E}^{(2,2)}} \text{mod } \varphi_E(E) + \sum_{E \subset S \cap \mathcal{E}^{(2,m)}} \text{mod } \varphi_E(A(E)) \leq \sum_{\beta} \frac{Mv(F(\beta))}{\deg(F|_\beta)} + C,$$

where the last sum is taken over all the curves β in $F^{-1}(\eta)$ for every $\eta \in Y$ such that β is homotopic to γ within $S = S \setminus \mathcal{P}$.

The right term is less than $Mv(\gamma) = \text{mod}(\phi_S(S))$ by (16). Therefore, as in the non-renormalizable case, one can embed holomorphically $\varphi_E(E)$ essentially into the interior of $\phi_S(S)$ for every $\mathcal{E}^2$ -piece $E \subset S$ according to the original order of their non-null-homotopic boundary curves, so that they are mutually disjoint. In other words, we have a quasi-conformal map ψ_S from S onto $\phi_S(S)$, such that

- $\psi_S|_{\partial S} = \phi_S|_{\partial S}$ and ψ_S is isotopic to ϕ_S rel ∂S ;
- for every $\mathcal{E}^2$ -piece $E \subset S$, $\varphi_E \circ \psi_S^{-1}$ is holomorphic in the interior of $\psi_S(E)$.

Consequently, we have

- $\phi_{\widehat{S}} \circ F \circ \psi_S^{-1}$ is holomorphic in the interior of $\psi_S(E)$ for every $\mathcal{E}^2$ -piece $E \subset S$ with $\widehat{S} := F(E)$.

Assume now that S is an $\mathcal{C}$ -piece and that A is an annular component of $S \setminus E_S$ where E_S is the unique complex $\mathcal{E}$ -piece contained in S . Following a similar argument as above, we have a quasi-conformal map ψ_A from A onto $\psi_S(A)$, such that

- $\psi_A|_{\partial A} = \psi_S|_{\partial A}$ and ψ_A is isotopic to $\psi_S|_A$ rel ∂A ;
- $\phi_{\widehat{S}} \circ F \circ \psi_A^{-1}$ is holomorphic in the interior of $\psi_A(E)$ for every $\mathcal{E}^2$ -piece $E \subset A$ with $\widehat{S} := F(E)$.

8.4 Definition of θ_S

Define $\theta_S = \phi_S^{-1} \circ \psi_S$ for every $\mathcal{A}$ -piece S . If S is a $\mathcal{C}$ -piece, define

$$\theta_S = \begin{cases} \phi_S^{-1} \circ \psi_A & \text{on every annular component } A \text{ of } S \setminus \mathcal{E}^m; \\ \phi_S^{-1} \circ \psi_S & \text{otherwise.} \end{cases}$$

Then $\theta_S|_{\partial S} = \text{id}$ and θ_S is isotopic to the identity rel $\partial S \cup (S \cap \mathcal{P})$. Moreover, for every $\mathcal{E}^2 \cup \mathcal{E}^m$ -piece E with $E \subset S$ and $F(E) = \widehat{S}$, the map $\phi_{\widehat{S}} \circ F \circ \theta_S^{-1} \phi_S^{-1}$ is holomorphic in the interior of $\phi_S \theta_S(E)$.

Now if $\mathcal{E}^0 \cup \mathcal{O} \cup \mathcal{R} = \emptyset$, the proof of Theorem 5.4 is already completed. Otherwise one can follow the argument as in the non-renormalizable case (there is no more trouble in case $\mathcal{R} \neq \emptyset$) to modify θ_S on $S \setminus (\mathcal{E}^2 \cup \mathcal{E}^m \cup \partial S)$ with the help of a suitable layer function. This ends the proof of Theorem 5.4. $\square$

9 A combination result

A *regular puzzle* is by definition a subset of $\overline{\mathbb{C}}$ which is also a puzzle surface.

A *regular open set* is by definition the complement of a regular puzzle.

Let U, V be regular open sets in $\overline{\mathbb{C}}$ with $V \subset \subset U$. Let $G : U \rightarrow V$ be a quasi-regular branched covering. We say that (G, U, V) is a *locally holomorphic attracting system*, if there is a finite set $\mathcal{P}' \subset U$ such that:

- $G(\mathcal{P}') = \mathcal{P}'$;
- G is holomorphic in a neighborhood of $\mathcal{P}'$ and each cycle in $\mathcal{P}'$ is (super)attracting;
- for any $z \in V$ the limit set of $\{G^n(z)\}$ is contained in $\mathcal{P}'$.

Let $F : \mathcal{E} \rightarrow \mathcal{L}$ be a repelling system of constant complexity, in particular F is quasi-regular. We say that F has no *analytization obstruction* if it has no boundary obstruction, and, for each renormalization $H : E \rightarrow S$ (if any, and not necessarily postcritically finite),

either

- (1) $\#\mathcal{P}_f \cap S < \infty$ and $(H, \mathcal{P}_F \cap S)$ as a repelling system has no Thurston obstructions; or
- (2) for the integer p such that $H = F^p|_E$, each step of the composition

$$E \xrightarrow{F} F(E) \xrightarrow{F} F^2(E) \xrightarrow{F} \dots \xrightarrow{F} F^{p-1}(E) \xrightarrow{F} S$$

is holomorphic in the interior.

What we have proved in this paper can be reformulate in the following stronger form:

Theorem 9.1. *Let G be a quasi-regular branched covering of $\overline{\mathbb{C}}$ with degree at least 2. Assume that $\overline{\mathbb{C}} = V \sqcup \mathcal{L}$ is a splitting with $\mathcal{L}$ a regular puzzle such that:*

- (a) $G^{-1}(V) \supset \supset V$;
- (b) $(G, G^{-1}(V), V)$ is a locally holomorphic attracting system;
- (c) $G : G^{-1}(\mathcal{L}) \rightarrow \mathcal{L}$ is a repelling system of constant complexity without analytization obstructions.

Let K be the union of the filled Julia set K_H of each of the holomorphic renormalizations.

Then there is a rational map g and a pair of qc-homeomorphisms ϕ, ψ of $\overline{\mathbb{C}}$ such that

- $\phi \circ G = g \circ \psi$;
- ψ is isotopic to ϕ rel $\mathcal{P}_G \cup K$;
- the Beltrami coefficient of ϕ is equal to 0 almost everywhere on K .

A Non-negative matrices

For a vector $v = (v_i) \in \mathbb{R}^n$ we write $v > 0$ if every coordinate v_i is strictly positive.

Lemma A.1. *Let $D = (a_{ij})$ be a real square matrix with $a_{ij} \geq 0$ for each entry a_{ij} . Denote by λ its spectral radius, i.e. the maximal modulus of the eigenvalues. Then $\lambda < 1$ iff there is a vector $v > 0$ such that $Dv < v$.*

Proof. The following proof is provided by H.H. Rugh. Necessity: Assume $v > 0$ and $Dv < v$. Then $Dv \leq av$ for some $0 \leq a < 1$. Define a norm on the underlying vector space by $\|x\| = \sum_i (v_i \cdot |x_i|)$. Then, writing $|x|$ as the vector whose i -th entry is $|x_i|$, we have

$$\|{}^t D x\| = {}^t v {}^t D |x| = {}^t (Dv) |x| \leq a {}^t v |x| = a \|x\|.$$

Therefore, $\lambda := \max_{\lambda' \text{ eigenvalue of } D} |\lambda'| = \max_{\lambda' \text{ eigenvalue of } {}^t D} |\lambda'| \leq \|{}^t D\| \leq a$.

Sufficiency: Now assume $\lambda < 1$. By continuity of the spectral radius, there is $\epsilon > 0$ such that the spectral radius λ_ϵ of $D + \epsilon := (a_{ij} + \epsilon)$ satisfies $\lambda_\epsilon < 1$. Now the Perron-Frobenius Theorem assures that λ_ϵ is also an eigenvalue (called the leading eigenvalue) and it has a strictly positive eigenvector $v > 0$. So $Dv \leq (D + \epsilon)v = \lambda_\epsilon v < v$. $\square$

Note that it follows that λ is also an eigenvalue of D (called the leading eigenvalue). Lemma A.1 actually gives an equivalent definition of the eigenvalues.

Corollary A.2. *Let $\lambda(D)$ be the leading eigenvalue of a non-negative square matrix D . Then*

$$\lambda(D) = \inf\{\lambda \mid \exists v > 0 \text{ such that } Dv < \lambda v\}.$$

Corollary A.3. *Assume that A and B are non-negative $n \times n$ matrix with $A \leq B$ (i.e. each entry of A is less than or equal to the corresponding entry of B), then $\lambda(A) \leq \lambda(B)$.*

Proof. From Lemma A.1, we see that for any $\lambda_0 > \lambda(B)$, there is a vector $v > 0$ so that $\lambda_0^{-1}Bv < v$. Thus $\lambda_0^{-1}Av \leq \lambda_0^{-1}Bv < v$. Again by Lemma A.1, we have $\lambda(A) < \lambda_0$ for any constant $\lambda_0 > \lambda(B)$. So $\lambda(A) \leq \lambda(B)$. $\square$

Let A be an $n \times n$ matrix with a block decomposition

$$\begin{pmatrix} B_{11} & \cdots & B_{1k} \\ \vdots & & \vdots \\ B_{k1} & \cdots & B_{kk} \end{pmatrix}$$

where B_{ij} is an $n_i \times n_j$ matrix (in particular each B_{ii} is a square matrix). We say that the block decomposition is *projected* if for each B_{ij} , there is a number b_{ij} such that the summation of each column of B_{ij} is equal to b_{ij} .

This property could be understood as the following: An $n \times n$ matrix can be considered as a linear map of $\mathbb{R}^n$ defined by the left action:

$$\begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} \mapsto A \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix}.$$

According to the block decomposition of A , there is a corresponding decomposition of the index set $I = \{1, \dots, n\}$ by $I = I_1 \sqcup \dots \sqcup I_k$ with $\#I_i = n_i$. Define a linear projection $\pi : \mathbb{R}^n \rightarrow \mathbb{R}^k$ by

$$(\pi v)_i = \sum_{\delta \in I_i} v_\delta.$$

Lemma A.4. *There is a $k \times k$ matrix B such that $\pi \circ A = B \circ \pi$ if and only if the block decomposition $A = (B_{ij})$ is projected. In this case, $B = (b_{ij})$.*

$$\begin{array}{ccc} \mathbb{R}^n & \xrightarrow{A} & \mathbb{R}^n \\ \pi \downarrow & & \downarrow \pi \\ \mathbb{R}^k & \xrightarrow{B} & \mathbb{R}^k \end{array}$$

Proof. Set $A = (a_{\delta\beta})$. For any $v \in \mathbb{R}^n$,

$$(\pi \circ Av)_i = \sum_j \sum_{\beta \in I_j} \left(\sum_{\delta \in I_i} a_{\delta\beta} \right) v_\beta, \quad \text{and} \quad (B \circ \pi(v))_i = \sum_j \sum_{\beta \in I_j} b_{ij} v_\beta.$$

If the block decomposition is projected, then for $\beta \in I_j$, $\sum_{\delta \in I_i} a_{\delta\beta} = b_{ij}$. Therefore $\pi \circ Av = B \circ \pi(v)$. Conversely, assume that $\pi \circ A = B \circ \pi$. For $\beta \in I_j$, let $e_\beta \in \mathbb{R}^n$ be a vector whose β -entry is 1 and 0 elsewhere. Then $(\pi \circ Ae_\beta)_i = b_{ij}$, and $(B \circ \pi(e_\beta))_i = \sum_{\delta \in I_i} a_{\delta\beta}$. So for $\beta \in I_j$, $\sum_{\delta \in I_i} a_{\delta\beta} = b_{ij}$, i.e. the block decomposition is projected. $\square$

Theorem A.5. *Assume that A is a non-negative square matrix with a projected block decomposition $A = (B_{ij})$. Set $B = (b_{ij})$. Then $\lambda(A) = \lambda(B)$.*

Proof. Let $v \neq 0$ be an eigenvector of A for the leading eigenvalue $\lambda(A)$, i.e. $Av = \lambda(A)v$. Set $u = \pi(v)$. Then $Bu = \pi \circ Av = \pi(\lambda(A)v) = \lambda(A)\pi(v) = \lambda(A)u$ by the above Lemma. So $\lambda(A)$ is an eigenvalue of B and hence $\lambda(A) \leq \lambda(B)$ since the leading eigenvalue is the maximum of the eigenvalues.

Conversely, let $u \neq 0$ be an eigenvector of the transpose B^t of B for the leading eigenvalue $\lambda(B)$ (note that B and B^t have same leading eigenvalues), i.e. $B^t u = \lambda(B)u$. Set $v = (v_\beta) \in \mathbb{R}^n$ by $v_\beta := u_j$ for $\beta \in I_j$. Then for $\delta \in I_i$,

$$(A^t v)_\delta = \sum_j \sum_{\beta \in I_j} a_{\beta\delta} v_\beta = \sum_j b_{ji} v_j = (B^t u)_i = \lambda(B)u_i = \lambda(B)v_\delta.$$

So $\lambda(B)$ is an eigenvalue of A^t . Therefore we again have $\lambda(B) \leq \lambda(A)$. $\square$

Corollary A.6. *Let A' be a non-negative square matrix with a block decomposition (B'_{ij}) . Assume that for each ij , the summation of each column of B'_{ij} is at most b_{ij} . Set $B = (b_{ij})$. Then $\lambda(A') \leq \lambda(B)$.*

Proof. For each ij , we just need to replace one entry of each column of B'_{ij} by a larger number so that the summation of the column becomes exactly b_{ij} . Denote by B_{ij} the modified matrix. Set $A = (B_{ij})$. Then $\lambda(A) = \lambda(B)$ by Theorem A.5 and $\lambda(A') \leq \lambda(A)$ by Corollary A.3. $\square$

B Reversing the Grötzsch inequality

A *equipotential* γ in a marked disc (Δ, a) is a curve mapped onto a round circle under a conformal representation $\varphi : (\Delta, a) \rightarrow (\mathbb{D}, 0)$. The potential of γ is defined to be the modulus of the annulus between $\partial\Delta$ and γ .

Lemma B.1. *Let (D_i, z_i) , $i = 1, 2$ be two disjoint marked hyperbolic discs. Then there is a constant $C > 0$ independent of $v_1 > 0, v_2 > 0$ such that, for the annulus $A(v_1, v_2)$ between the equipotential in D_1 of potential v_1 and the equipotential of D_2 of potential v_2 , we have*

$$v_1 + v_2 \leq \text{mod}(A(v_1, v_2)) \leq v_1 + v_2 + C$$

Proof. The left hand side is just the Grötzsch inequality.

The conformal radius of a marked disc $(\Delta, 0)$ is defined to be the radius r if there is a conformal map $\varphi : (\Delta, 0) \rightarrow (D(0, r), 0)$ with $\varphi'(0) = 1$. And the conformal radius of a marked disc $(\tilde{\Delta}, \infty)$ is defined to be the conformal radius of $(\pi(\tilde{\Delta}), 0)$ with $\pi(z) = 1/z$.

Let ξ be a Möbius transformation of $\overline{\mathbb{C}}$ with $\xi(z_1) = 0$ and $\xi(z_2) = \infty$. Any two such maps differ by a multiplicative constant. So the product $C_1 \cdot C_2$ of the conformal radii of $(\xi(D_1), 0)$ and $(\xi(D_2), \infty)$ is independent of the choice of ξ . Denote by W_i the component of $A(v_1, v_2)^c$ containing z_i , $i = 1, 2$. By Koebe 1/4-Theorem, $\xi(W_1)$ contains $\{|z| \leq C_1 r_1/4\}$ and $\xi(W_2)$ contains $\{|z| \geq 4/(C_2 r_2)\}$, where $r_i = e^{-v_i}$. Therefore

$$\text{mod}(A(v_1, v_2)) \leq \log\left(\frac{4}{C_2 r_2} \cdot \frac{4}{C_1 r_1}\right) = \log\left(\frac{16}{C_1 C_2} \frac{1}{r_1 r_2}\right) = \log \frac{16}{C_1 C_2} + v_1 + v_2. \quad \square$$

C Quasi-conformal extensions

We state here several results about quasi-conformal maps that have been frequently used in the paper.

Lemma C.1. *Let $h : C_1 \rightarrow C_2$ be a homeomorphism between two quasi-circles C_1 and C_2 in $\overline{\mathbb{C}}$. If h can be extended to a quasi-conformal map on an one-side neighborhood of C_1 , then h can be extended to a global quasi-conformal homeomorphism of $\overline{\mathbb{C}}$. Moreover the extension can be chosen to be a diffeomorphism from $\overline{\mathbb{C}} \setminus C_1$ onto $\overline{\mathbb{C}} \setminus C_2$.*

Lemma C.2. Let $\Omega_i \subset \overline{\mathbb{C}}$ ($i = 1, 2$) be two open connected domains such that $\partial\Omega_i$ ($i = 1, 2$) consists of $p \geq 0$ disjoint quasi circles (we allow the case $p = 0$). Let $\mathcal{P} \subset \Omega_1$ be a finite set (may or may not be empty). Let $f : \overline{\Omega}_1 \rightarrow \overline{\Omega}_2$ be an orientation preserving homeomorphism. If, either $p = 0$, or $f|_{\partial\Omega_1}$ can be extended to a quasi-conformal map on an one-side neighborhood of each curve of $\partial\Omega_1$, then there is a quasi-conformal homeomorphism in the isotopy class of f modulo $\partial\Omega_1 \cup \mathcal{P}$.

Lemma C.3. Let $h : S^1 \rightarrow S^1$ be an orientation preserving homeomorphism of the unit circle. Assume that h can be extended as a quasi-conformal map f on an inner neighborhood B of S^1 (i.e. $B \supset \{1 - \varepsilon < |z| < 1\}$ for some $\varepsilon > 0$), then h is quasi-symmetric.

Proof. Denote by μ the Beltrami coefficient of f . Denote by $\mathbb{D}$ the unit disc. Let $\nu = \mu$ on B and $\nu = 0$ on $\mathbb{D} \setminus B$. By the Measurable Riemann Mapping Theorem, there is a quasi-conformal homeomorphism g of $\mathbb{D}$ whose Beltrami coefficient is ν . Then $g|_{S^1}$ is quasi-symmetric. On the other hand, $f \circ g^{-1}$ is holomorphic on $g(B)$. Therefore $f \circ g^{-1}|_{S^1} : S^1 \rightarrow S^1$ is real-analytic, in particular quasi-symmetric. So $h = (f \circ g^{-1}) \circ g|_{S^1}$ is also quasi-symmetric. $\square$

Proof of Lemma C.1. Fix $i = 1, 2$. By definition of quasi-circles, there is a quasi-conformal homeomorphism ϕ_i of $\overline{\mathbb{C}}$ such that $\phi_i(C_i) = S^1$. Furthermore ϕ_i can be chosen to be diffeomorphism on $\overline{\mathbb{C}} \setminus C_i$ as follows: Set $\Delta = \phi_i^{-1}(\mathbb{D})$. Let $\psi : \Delta \rightarrow \mathbb{D}$ be a conformal map. Then $\phi_i \circ \psi^{-1} : \mathbb{D} \rightarrow \mathbb{D}$ is a quasi-conformal homeomorphism. Thus its boundary map is quasi-symmetric. Let η be the Beurling-Ahlfors extension of this boundary map, it is a diffeomorphism of $\mathbb{D}$. Now $\eta \circ \psi|_{\Delta}$ is again a diffeomorphism, whose boundary map is $\phi_i|_{S^1}$. Set $h_1 = \phi_2 \circ h \circ \phi_1^{-1}$. Then by Lemma C.3 this h_1 is quasi-symmetric, thus has a quasi-conformal extension to $\overline{\mathbb{C}}$. Moreover its extension can be chosen to be a diffeomorphism outside S^1 . Thus $h = \phi_2^{-1} \circ h_1 \circ \phi_1$ can be extended to a quasi-conformal homeomorphism of $\overline{\mathbb{C}}$, and a diffeomorphism outside C_1 . $\square$

Proof of Lemma C.2. By Lemma C.1 we can assume that $\partial\Omega_i$ are smooth Jordan curves and that $f|_{\partial\Omega_1}$ is a diffeomorphism. Then one can find a diffeomorphism in its isotopy class rel $\partial\Omega_1 \cup \mathcal{P}$. $\square$

D A lemma about isotopy

Lemma D.1. Let $(D_i, a_i), i = 1, \dots, k, k \geq 1$ be finitely many marked Jordan discs in S^2 , with disjoint closures. Let P be a closed (or empty) set contained in $S^2 \setminus \bigcup \overline{D_i}$. Assume that $h_1 : S^2 \rightarrow S^2$ is an orientation preserving homeomorphism, and $h : S^2 \times [0, 1] \rightarrow S^2$ is continuous, such that

- a) $h_1|_{P \cup \bigcup D_i} = id$
- b1) $h(\cdot, t)$ is a homeomorphism for any $t \in [0, 1]$;
- b2) $h(\cdot, 0) = id, h(\cdot, 1) = h_1$;
- b3) $h(x, t) = x$ for any $x \in P \cup \bigcup \{a_i\}$ and any $t \in [0, 1]$.

For $i = 1, \dots, k$, set $\gamma_i = \partial D_i$, and let β_i be a Jordan curve disjoint from $\overline{D_i}$ so that the annuli $A_i := A(\beta_i, \gamma_i)$ have mutually disjoint closures and are disjoint from P . Then there is a continuous map $H : S^2 \times [0, 1] \rightarrow S^2$ such that

- c1) $H(\cdot, t)$ is a homeomorphism for any $t \in [0, 1]$;
- c2) $H(\cdot, 0) = id, H(\cdot, 1) = h_1 \circ T$ with $T = id$ outside $\bigcup A_i$;
- c3) $H(x, t) = x$ for any $x \in P \cup \bigcup D_i$ and any $t \in [0, 1]$.

Proof. Set $h_t = h(\cdot, t)$, and $E = S^2 \setminus \bigcup (D_i \cup A_i)$.

For each i choose a Jordan curve α_i in D_i bounding a disc $D(\alpha_i)$ so that $a_i \in D(\alpha_i) \subset D_i$ and that $h_t(\beta_i) \cap \alpha_i = \emptyset$ for any $t \in [0, 1]$.

Define $s : S^2 \times [0, 1] \rightarrow S^2$ continuous, with each $s(\cdot, t) := s_t$ a homeomorphism of S^2 , as follows: $s(\cdot, 0) = id$.

$$s(x, t) = \begin{cases} h_t^{-1}(x) & x \in \bigcup D(\alpha_i) \\ \text{interpolation} & x \in \bigcup A(\alpha_i, \beta_i) \\ x & x \in E \end{cases} . \text{ Then } s(x, 1) = \begin{cases} x = h_1^{-1}(x) & x \in \bigcup D(\alpha_i) \\ T_0(x) & x \in \bigcup A(\alpha_i, \beta_i) \\ x & x \in E \end{cases} ,$$

where T_0 is a certain homeomorphism of S^2 that is identity outside $\bigcup A(\alpha_i, \beta_i)$.

$$\text{Set } \xi_t = h_t \circ s_t. \text{ Then } \xi_0 = id, \quad \xi_t(x) = \begin{cases} x & x \in \bigcup D(\alpha_i) \\ \text{interpolation} & x \in \bigcup A(\alpha_i, \beta_i) \\ h_t(x) & x \in E \\ x = h_t(x) & x \in P \subset E \end{cases} ,$$

$$\text{and } \xi_1(x) = h_1 \circ s_1(x) = \begin{cases} x = h_1(x) & x \in \bigcup D(\alpha_i) \\ h_1 \circ T_0(x) & x \in \bigcup A(\alpha_i, \beta_i) \\ h_1(x) & x \in E \\ x = h_1(x) & x \in P \subset E \end{cases} .$$

Let now $u : S^2 \rightarrow S^2$ be a homeomorphism such that $u(D_i) = D(\alpha_i)$, $u(a_i) = a_i$ for each i and $u|_E = id$. Define then $v : S^2 \rightarrow S^2$ be a homeomorphism such that $v|_{\bigcup D(\alpha_i)} = u^{-1}$ and

$$v|_{h_1(E) \cup E} = id. \text{ Set } \zeta_t = v \circ \xi_t \circ u. \text{ We have } \zeta_0 = \begin{cases} id & x \notin \bigcup A_i \\ v \circ u & x \in \bigcup A_i \end{cases} ,$$

$$\zeta_t(x) = \begin{cases} x = h_1(x) & x \in \bigcup D_i \\ \text{interpolation} & x \in \bigcup A_i \\ v \circ h_t(x) & x \in E \\ x = h_1(x) & x \in P \subset E \end{cases} , \quad \zeta_1(x) = \begin{cases} x = h_1(x) & x \in \bigcup D_i \\ v \circ h_1 \circ T_0 \circ u(x) & x \in \bigcup A_i \\ h_1(x) & x \in E \\ x = h_1(x) & x \in P \subset E \end{cases} = h_1 \circ$$

$T_1(x)$

for a certain homeomorphism T_1 of S^2 with $T_1 = id$ outside $\bigcup A_i$. Set finally $H_t(x) = \zeta_t \circ$

$$\zeta_0^{-1}(x). \text{ It has the required properties. In particular } H(\cdot, 1) = \begin{cases} h_1 & x \notin \bigcup A_i \\ v \circ h_1 \circ T_0 \circ v^{-1} & x \in \bigcup A_i \end{cases} =$$

$h_1 \circ T_1 \circ T_2$, with $T_2 = \zeta_0^{-1}$, and $T_1 \circ T_2 = id$ outside $\bigcup_i A_i$. $\square$
